# Robust dynamic panel data models using epsilon-contamination 

Badi H Baltagi<br>Georges Bresson<br>Anoop Chaturvedi<br>Guy Lacroix

## Robust dynamic panel data models using epsilon-contamination

This paper extends the work of Baltagi et al (2018) to the popular dynamic panel data model. We investigate the robustness of Bayesian panel data models to possible misspecification of the prior distribution. The proposed robust Bayesian approach departs from the standard Bayesian framework in two ways. First, we consider the epsilon-contamination class of prior distributions for the model parameters as well as for the individual effects. Second, both the base elicited priors and the epsilon-contamination priors use Zellner's (1986) $g$-priors for the variancecovariance matrices. We propose a general "toolbox" for a wide range of specifications which includes the dynamic panel model with random effects, with cross-correlated effects à la Chamberlain, for the Hausman-Taylor world and for dynamic panel data models with homogeneous/heterogeneous slopes and crosssectional dependence. Using a Monte Carlo simulation study, we compare the finite sample properties of our proposed estimator to those of standard classical estimators. The paper contributes to the dynamic panel data literature by proposing a general robust Bayesian framework which encompasses the conventional frequentist specifications and their associated estimation methods as special cases.

## 1. Introduction

The dynamic panel data model allows for feedback from lagged endogenous values and have been used in many empirical studies. The most popular estimation method is the generalized method of moments (GMM) with many variants, the best known being the Arellano-Bond difference GMM and the Blundell-Bond system GMM (see Arellano and Bond (1991), Blundell and Bond (1998) and the survey by Bun and Sarafidis (2015)). Despite its optimal asymptotic properties, the finite sample behavior of the GMM estimator can be poor due to weakness and/or abundance of moment conditions and dependence on crucial nuisance parameters. Several alternative inference methods derived from inconsistent least squares (LS) or likelihood based procedures have been proposed. These include modifications of the profile likelihood (Dhaene and Jochmans, 2011, 2016) or estimation methods based on the likelihood function of the first differences (Hsiao et al., 2002; Hayakawa and Pesaran, 2015).

While GMM estimation is very attractive because of its flexibility, other promising methods remain underrepresented in empirical work. Examples are bias-correction procedures for the fixedeffects dynamic panel estimator proposed by Kiviet (1995), Bun (2003), Everaert and Pozzi (2007) among others. Estimation of dynamic panel data models with heterogeneous slopes and/or crosssectional dependence has also been investigated by Chudik and Pesaran (2015a,b) using the common correlated effects (CCE) approach of Pesaran (2006), and by Moon and Weidner (2015, 2017), who studied linear models with interactive fixed effects.

Quasi-maximum likelihood (QML) methods have been also proposed to circumvent the aforementioned bias by modeling the unconditional likelihood function instead of conditioning on the initial observations. While this requires additional assumptions on the marginal distribution of the initial observations, the QML estimators are an attractive alternative to other estimation approaches in terms of efficiency and finite-sample performance if all the assumptions are satisfied. QML estimators can be characterized as limited-information maximum likelihood estimators that are special cases of structural equation modeling or full information maximum-likelihood approach with many cross-equation restrictions ${ }^{1}$. For dynamic models with random effects, we must be explicit about the non-zero correlation between the individual-specific effects and the initial conditions (see Anderson and Hsiao (1982), Hsiao and Pesaran (2008), Kripfganz (2016), Bun et al. (2017), Moral-Benito et al. (2019)). ${ }^{2}$

The widely used difference GMM estimator suffers from finite sample bias when the number of cross-section observations is small. Moreover, some have expressed concern in recent years that many instrumental variables of the type considered in panel GMM estimators may be invalid, weak or both (see Bun and Sarafidis (2015)). Based on the same identifying assumption, some alternatives have been proposed in the literature (e.g. Ahn and Schmidt (1995) and Hsiao et al. (2002), to mention a few). Maximum likelihood estimators, asymptotically equivalent to the GMM estimator, have recently been proposed and are strongly preferred in terms of finite sample performance (MoralBenito et al. (2019)).

Bayesian analysis for dynamic panel data models have also been proposed (see for instance

[^0]Hsiao et al. (1999), Hsiao and Pesaran (2008), Koop et al. (2008), Juárez and Steel (2010), Liu et al. (2017), Bretó et al. (2019), Pacifico (2019)). Some consider that the process which generates the initial observation $y_{i 0}$ of the dependent variable for each individual $i$ has started a long time ago (e.g., Juárez and Steel (2010)). Others derive the estimators under the assumption that $y_{i 0}$ are fixed constants (e.g., Hsiao et al. (1999), Hsiao and Pesaran (2008)). Yet others consider that the initial value is generated from the finite past using state space forms (e.g., Liu et al. (2017)), or use the Prais-Winsten transformation for the initial period. A simplifying approach, more feasible for large $T$, is to condition on the first observation in a model involving a first-order lag in $y$, so that $y_{i 1}$ is nonstochastic (see Bauwens et al. (2005)). Geweke and Keane (2000) consider Bayesian approaches to the dynamic linear panel model in which the model for period 1 is not necessarily linked to those for subsequent periods in a way consistent with stationarity.

This brief overview seems to confirm the strong comeback of ML methods and associated Bayesian approaches for dynamic panel data models. MCMC holds some advantages over ML or QML estimation. For instance, Su and Yang (2015) have discussed issues involved in maximizing a concentrated version of the likelihood function that could involve trivariate optimization over the parameters and subject to stationarity restrictions. This type of constrained optimization may lead to local optima and may produce misleading inference. In our earlier paper (Baltagi et al., 2018), which considered a static panel data model, we argued that the Bayesian approach rests upon hypothesized prior distributions (and possibly on their hyperparameters). The choice of specific distributions is often made out of convenience. Yet, it is well-known that the estimators can be sensitive to misspecification of the latter. Fortunately, this difficulty can be partly circumvented by use of the robust Bayesian approach which relies upon a class of prior distributions and selects an appropriate one in a data dependent fashion. This paper extends our earlier paper to the popular dynamic panel data model and studies the robustness of Bayesian panel data models to possible misspecification of the prior distribution in the spirit of the works of Good (1965), Berger (1985) and Berger and Berliner (1984, 1986). In particular, it is concerned with the posterior robustness which is different from the robustness à la White (1980). The objective of our paper is to propose a robust Bayesian approach for dynamic panel data models which departs from the standard Bayesian one in two ways. First, we consider the $\varepsilon$-contamination class of prior distributions for the model parameters (and for the individual effects). Second, both the base elicited priors and the $\varepsilon$-contamination priors use Zellner (1986)'s $g$-priors rather than the standard Wishart distributions for the variance-covariance matrices. We propose a general "toolbox" for a wide range of specifications such as the dynamic panel model with random effects, or with cross-correlated effects $\grave{a} l a$ Mundlak or à la Chamberlain, for the Hausman-Taylor world or for dynamic panel data models with homogeneous/heterogeneous slopes and cross-sectional dependence. The paper contributes to the dynamic panel data literature by proposing a general robust Bayesian framework which encompasses all the above-mentioned conventional frequentist specifications and their associated estimation methods as special cases.

Section 2 gives the general framework of a robust linear dynamic panel data model using $\varepsilon$-contamination and derives the Type-II maximum likelihood posterior mean and the variancecovariance matrix of the coefficients in a two-stage hierarchy model. Section 3 investigates the finite sample performance of our robust Bayesian estimator through extensive Monte Carlo experiments. The simulation results underscore the relatively good performance of the two-stage hierarchy estimator as compared to the standard frequentist estimation methods. Section 4 gives our conclusion.

## 2. A robust linear dynamic panel data model

### 2.1. The static framework

Baltagi et al. (2018) considered the following Gaussian static linear mixed model:

$$
\begin{equation*}
y_{i t}=X_{i t}^{\prime} \beta+W_{i t}^{\prime} b_{i}+u_{i t}, i=1, \ldots, N, t=1, \ldots, T \tag{1}
\end{equation*}
$$

where $X_{i t}^{\prime}$ is a $\left(1 \times K_{x}\right)$ vector of explanatory variables including the intercept, and $\beta$ is a $\left(K_{x} \times 1\right)$ vector of parameters. $t$ is the faster index (primal pooling). Furthermore, let $W_{i t}^{\prime}$ denote a $\left(1 \times k_{2}\right)$ vector of covariates and $b_{i}$ a $\left(k_{2} \times 1\right)$ vector of parameters. The subscript $i$ of $b_{i}$ indicates that the model allows for heterogeneity on the $W$ variables. The distribution of $u_{i t}$ is parametrized in terms of its precision $\tau$ rather than its variance $\sigma_{u}^{2}(=1 / \tau) .^{3}$

Following the seminal papers of Lindley and Smith (1972) and Smith (1973), various authors including Chib and Carlin (1999), Koop (2003), Chib (2008), Greenberg (2008), Zheng et al. (2008), and Rendon (2013) have proposed a very general three-stage hierarchy framework

$$
\text { First stage : } \quad y=X \beta+W b+u, u \sim N(0, \Sigma), \Sigma=\tau^{-1} I_{N T}
$$

Second stage: $\quad \beta \sim N\left(\beta_{0}, \Lambda_{\beta}\right)$ and $b \sim N\left(b_{0}, \Lambda_{b}\right)$

$$
\text { Third stage : } \quad \Lambda_{b}^{-1} \sim W i s h\left(\nu_{b}, R_{b}\right) \text { and } \tau \sim G(\cdot)
$$

where $y=\left(y_{1,1}, \ldots, y_{1, T}, \ldots, y_{N, 1}, \ldots, y_{N, T}\right)^{\prime}$ is $(N T \times 1) . X$ is $\left(N T \times K_{x}\right), W$ is $\left(N T \times K_{2}\right)$ with $K_{2}=N k_{2}, u$ is $(N T \times 1)$ and $I_{N T}$ is a $(N T \times N T)$ identity matrix. TO better understand the difference between $X_{i t}^{\prime} \beta$ and $W_{i t}^{\prime} b_{i}$ (or $X \beta$ and $W b$ for the $N T$ observations), we provide the following examples of $W b$ which we will use in the dynamic version in Section 3 of the Monte Carlo simulation study. ${ }^{4}$ In the random effects world, $W b=Z_{\mu} \mu$ with $Z_{\mu}=I_{N} \otimes \iota_{T}$ being of dimension $(N T \times N), \otimes$ is the Kronecker product, $\iota_{T}$ is a $(T \times 1)$ vector of ones and $\mu$ is a $(N \times 1)$ vector of idiosyncratic parameters. When $W \equiv Z_{\mu}$, the random effects are $\mu \sim N\left(0, \sigma_{\mu}^{2} I_{N}\right)$. For a Chamberlain-type fixed effects world, the individual effects are given by $\mu=\underline{X} \Pi+\varpi$, where $\underline{X}$ is a $\left(N \times T K_{x}\right)$ matrix with $\underline{X}_{i}=\left(X_{i 1}^{\prime}, \ldots, X_{i T}^{\prime}\right)$ and $\Pi=\left(\pi_{1}^{\prime}, \ldots, \pi_{T}^{\prime}\right)^{\prime}$ is a $\left(T K_{x} \times 1\right)$ vector. The model can be rewritten as: $y=X \beta+Z_{\mu} \underline{X} \Pi+Z_{\mu} \varpi+u=Z \theta+Z_{\mu} \varpi+u$ with $Z=\left[X, Z_{\mu} \underline{X}\right]$ and let $W b \equiv Z_{\mu} \varpi$ with $\varpi \sim N\left(0, \sigma_{\varpi}^{2} I_{N}\right)$. For the Hausman-Taylor world, $y=X \beta+V \eta+Z_{\mu} \mu+u$, where $V$ is a vector of time-invariant variables, and subsets of $X$ and $V$ may be correlated with the individual effects $\mu$, but leaves the correlations unspecified. Then, $y=Z \theta+W b+u$ with $Z=[X, V]$ and $W b=Z_{\mu} \mu$ with $\mu \sim N\left(0, \sigma_{\mu}^{2} I_{N}\right)$. For the panel data world with common correlated effects (or common trends), $y=X \beta+W b+u=X \beta+F \Gamma+u$ where the $(N T \times N m$ ) matrix $F$ of the $m$ unobserved factors (or common trends) is a blockdiagonal matrix where each ( $T \times m$ ) sub block $f$ is replicated $N$ times and $\Gamma$ is the $(N m \times 1)$ individual varying coefficients vector.

The parameters depend upon hyperparameters which themselves follow random distributions. The second stage (also called fixed effects model in the Bayesian literature) updates the distribution of the parameters. The third stage (also called random effects model in the Bayesian literature)

[^1]updates the distribution of the hyperparameters. The random effects model simply updates the distribution of the hyperparameters. The precision $\tau$ is assumed to follow a Gamma distribution and $\Lambda_{b}^{-1}$ is assumed to follow a Wishart distribution with $\nu_{b}$ degrees of freedom and a hyperparameter matrix $R_{b}$ which is generally chosen close to an identity matrix. In that case, the hyperparameters only concern the variance-covariance matrix of the $b$ coefficients and the precision $\tau$. As is well-known, Bayesian methods are sensitive to misspecification of the distributions of the priors. Conventional proper priors in the normal linear model have been based on the conjugate NormalGamma family because they allow closed form calculations of all marginal likelihoods. Likewise, rather than specifying a Wishart distribution for the variance-covariance matrices as is customary, Zellner's $g$-prior $\left(\Lambda_{\beta}=\left(\tau g X^{\prime} X\right)^{-1}\right.$ for $\beta$ or $\Lambda_{b}=\left(\tau h W^{\prime} W\right)^{-1}$ for $b$ ) has been widely adopted because of its computational efficiency in evaluating marginal likelihoods and because of its simple interpretation arising from the design matrix of observables in the sample. Since the calculation of marginal likelihoods using a mixture of $g$-priors involves only a one-dimensional integral, this approach provides an attractive computational solution that made the original $g$-priors popular while insuring robustness to misspecification of $g$ (see Zellner (1986)).

To guard against mispecifying the distributions of the priors, Baltagi et al. (2018) considered the $\varepsilon$-contamination class of prior distributions for $(\beta, b, \tau)$ :

$$
\begin{equation*}
\Gamma=\left\{\pi\left(\beta, b, \tau \mid g_{0}, h_{0}\right)=(1-\varepsilon) \pi_{0}\left(\beta, b, \tau \mid g_{0}, h_{0}\right)+\varepsilon q\left(\beta, b, \tau \mid g_{0}, h_{0}\right)\right\} \tag{3}
\end{equation*}
$$

where $\pi_{0}(\cdot)$ is the base elicited prior, $q(\cdot)$ is the contamination belonging to some suitable class $Q$ of prior distributions, and $0 \leq \varepsilon \leq 1$ reflects the amount of error in $\pi_{0}(\cdot) . \tau$ is assumed to have a vague prior, $p(\tau) \propto \tau^{-1}, 0<\tau<\infty$, and $\pi_{0}\left(\beta, b, \tau \mid g_{0}, h_{0}\right)$ is the base prior assumed to be a specific $g$-prior with

$$
\left\{\begin{align*}
\beta & \sim N\left(\beta_{0} \iota_{K_{x}},\left(\tau g_{0} \Lambda_{X}\right)^{-1}\right) \text { with } \Lambda_{X}=X^{\prime} X  \tag{4}\\
b & \sim N\left(b_{0} \iota_{K_{2}},\left(\tau h_{0} \Lambda_{W}\right)^{-1}\right) \text { with } \Lambda_{W}=W^{\prime} W
\end{align*}\right.
$$

where $\iota_{K_{x}}$ is a $\left(K_{x} \times 1\right)$ vector of ones. Here, $\beta_{0}, b_{0}, g_{0}$ and $h_{0}$ are known scalar hyperparameters of the base prior $\pi_{0}\left(\beta, b, \tau \mid g_{0}, h_{0}\right)$. The probability density function (henceforth pdf) of the base prior $\pi_{0}($.$) is given by:$

$$
\begin{equation*}
\pi_{0}\left(\beta, b, \tau \mid g_{0}, h_{0}\right)=p\left(\beta \mid b, \tau, \beta_{0}, b_{0}, g_{0}, h_{0}\right) \times p\left(b \mid \tau, b_{0}, h_{0}\right) \times p(\tau) \tag{5}
\end{equation*}
$$

The possible class of contamination $Q$ is defined as:

$$
Q=\left\{\begin{array}{c}
q\left(\beta, b, \tau \mid g_{0}, h_{0}\right)=p\left(\beta \mid b, \tau, \beta_{q}, b_{q}, g_{q}, h_{q}\right) \times p\left(b \mid \tau, b_{q}, h_{q}\right) \times p(\tau)  \tag{6}\\
\text { with } 0<g_{q} \leq g_{0}, 0<h_{q} \leq h_{0}
\end{array}\right\}
$$

with

$$
\left\{\begin{align*}
\beta & \sim N\left(\beta_{q} \iota_{K_{x}},\left(\tau g_{q} \Lambda_{X}\right)^{-1}\right)  \tag{7}\\
b & \sim N\left(b_{q} \iota_{K_{2}},\left(\tau h_{q} \Lambda_{W}\right)^{-1}\right)
\end{align*}\right.
$$

where $\beta_{q}, b_{q}, g_{q}$ and $h_{q}$ are unknown. The restrictions $g_{q} \leq g_{0}$ and $h_{q} \leq h_{0}$ imply that the base prior is the best possible so that the precision of the base prior is greater than any prior belonging to the contamination class. The $\varepsilon$-contamination class of prior distributions for $(\beta, b, \tau)$ is then conditional on known $g_{0}$ and $h_{0}$.

Following Baltagi et al. (2018) for the static panel model, we use a two-step strategy because it simplifies the derivation of the predictive densities (or marginal likelihoods). ${ }^{5}$ This will be extended to the dynamic panel model introduced in the next section.

### 2.2. The dynamic framework

This paper considers the Gaussian dynamic linear mixed model:

$$
\begin{equation*}
y_{i t}=\rho y_{i t-1}+X_{i t}^{\prime} \beta+W_{i t}^{\prime} b_{i}+u_{i t}=Z_{i t}^{\prime} \theta+W_{i t}^{\prime} b_{i}+u_{i t}, i=1, \ldots, N, t=2, \ldots, T \tag{8}
\end{equation*}
$$

where $Z_{i t}^{\prime}=\left[y_{i t-1}, X_{i t}^{\prime}\right]$ and $\theta^{\prime}=\left[\rho, \beta^{\prime}\right]$ are $\left(1 \times K_{1}\right)$ vectors with $K_{1}=K_{x}+1$. The likelihood is conditional on the first period observations $y_{1}$. In that case, the first period is assumed exogenous and known. In the spirit of (2), we have the following:

$$
\begin{align*}
\text { First stage : } & y=\rho y_{-1}+X \beta+W b+u, u \sim N(0, \Sigma), \Sigma=\tau^{-1} I_{N(T-1)} \\
\text { Second stage : } & \beta \sim N\left(\beta_{0}, \Lambda_{\beta}\right) \text { and } b \sim N\left(b_{0}, \Lambda_{b}\right)  \tag{9}\\
\text { with } & p(\tau) \propto \tau^{-1}, \Lambda_{\beta}=\left(\tau g X^{\prime} X\right)^{-1} \text { and } \Lambda_{b}=\left(\tau h W^{\prime} W\right)^{-1}
\end{align*}
$$

where $y=\left(y_{1,2}, \ldots, y_{1, T}, \ldots, y_{N, 2}, \ldots, y_{N, T}\right)^{\prime}$ and $y_{-1}=\left(y_{1,1}, \ldots, y_{1, T-1}, \ldots, y_{N, 1}, \ldots, y_{N, T-1}\right)^{\prime}$ are $(N(T-1) \times 1)$. $X$ is $\left(N(T-1) \times K_{x}\right), W$ is $\left(N(T-1) \times K_{2}\right), u$ is $(N(T-1) \times 1)$ and $I_{N(T-1)}$ is a $(N(T-1) \times N(T-1))$ identity matrix.

There is an extensive literature on autoregressive processes using Bayesian methods. The stationarity assumption implies that the autoregressive time dependence parameter space for $\rho$ is a compact subset of $(-1,1)$. For the pros and cons of imposing a stationarity hypothesis in a Bayesian setup see Phillips (1991). Ghosh and Heo (2003) proposed a comparative study using some selected noninformative (objective) priors for the $A R(1)$ model. Ibazizen and Fellag (2003), assumed a noninformative prior for the autoregressive parameter without considering the stationarity assumption for the $\mathrm{AR}(1)$ model. However, most papers consider a noninformative (objective) prior for the Bayesian analysis of an $A R(1)$ model without considering the stationarity assumption. See for example Sims and Uhlig (1991). For the dynamic random coefficients panel data model, Hsiao and Pesaran (2008) do not impose any constraint on the coefficients of the lag dependent variable, $\rho_{i}$. But, one way to impose the stability condition on individual units would be to assume that $\rho_{i}$ follows a rescaled Beta distribution on $(0,1)$. In the time series framework, and for an $A R(1)$ model, Karakani et al. (2016) have performed a posterior sensitivity analysis based on Gibbs sampling with four different priors: natural conjugate prior, Jeffreys' prior, truncated normal prior and $g$-prior. Their respective performances are compared in terms of the highest posterior density region criterion. They show that the truncated normal distribution outperforms very slightly the $g$-prior and more strongly the other priors especially when the time dimension is small. On the other hand, for a larger time span, there is no significant difference between the truncated normal distribution and the $g$-prior.

Nevertheless, introducing a truncated normal distribution for $\rho$ poses very complex integration problems due to the presence of the normal cdf function as integrand in the marginal likelihoods with $\varepsilon$-contamination class of prior distributions. To avoid these problems, $\rho$ could be assumed

[^2]to be $U(-1,1)$. In that case, its mean (0) and its variance $(1 / 3)$ are exactly defined and we do not need to introduce an $\varepsilon$-contamination class of prior distributions for $\rho$ at the second stage of the hierarchy. This was initially our first goal. Unfortunately, the results using Monte Carlo simulations showed biased estimates of $\rho, \beta$ and residual variances (see Appendices A. 1 and A. 2 in the supplementary material). Consequently, we assume a Zellner $g$-prior for $\theta\left(=\left[\rho, \beta^{\prime}\right]^{\prime}\right)$ which encompasses the coefficient of the lagged dependent variable $y_{i, t-1}$ and those of the explanatory variables $X_{i t}^{\prime}$. In other words, the two-stage hierarchy becomes.
\[

$$
\begin{align*}
\text { First stage : } & y=Z \theta+W b+u, u \sim N(0, \Sigma), \Sigma=\tau^{-1} I_{N(T-1)} \\
\text { Second stage : } & \theta \sim N\left(\theta_{0}, \Lambda_{\theta}\right) \text { and } b \sim N\left(b_{0}, \Lambda_{b}\right)  \tag{10}\\
\text { with } & p(\tau) \propto \tau^{-1}, \Lambda_{\theta}=\left(\tau g Z^{\prime} Z\right)^{-1} \text { and } \Lambda_{b}=\left(\tau h W^{\prime} W\right)^{-1}
\end{align*}
$$
\]

Thus, we do not impose stationarity constraints like many authors and we respect the philosophy of $\varepsilon$-contamination class using data-driven priors.

### 2.3. The robust dynamic linear model in the two-stage hierarchy

Using a two-step approach, we can integrate first with respect to $(\theta, \tau)$ given $b$ and then, conditional on $\theta$, we integrate with respect to $(b, \tau)$.

1. Let $y^{*}=(y-W b)$. Derive the conditional ML-II posterior distribution of $\theta$ given the specific effects $b$.
2. Let $\widetilde{y}=(y-Z \theta)$. Derive the conditional ML-II posterior distribution of $b$ given the coefficients $\theta$.

Thus, the marginal likelihoods (or predictive densities) corresponding to the base priors are:

$$
m\left(y^{*} \mid \pi_{0}, b, g_{0}\right)=\int_{0}^{\infty} \int_{\mathbb{R}^{K_{1}}} \pi_{0}\left(\theta, \tau \mid g_{0}\right) \times p\left(y^{*} \mid Z, b, \tau\right) d \theta d \tau
$$

and

$$
m\left(\widetilde{y} \mid \pi_{0}, \theta, h_{0}\right)=\int_{0}^{\infty} \int_{\mathbb{R}^{K_{2}}} \pi_{0}\left(b, \tau \mid h_{0}\right) \times p(\widetilde{y} \mid W, \theta, \tau) d b d \tau
$$

with

$$
\begin{aligned}
& \left.\pi_{0}\left(\theta, \tau \mid g_{0}\right)=\left(\frac{\tau g_{0}}{2 \pi}\right)^{\frac{K_{1}}{2}} \tau^{-1}\left|\Lambda_{Z}\right|^{1 / 2} \exp \left(-\frac{\tau g_{0}}{2}\left(\theta-\theta_{0} \iota_{K_{1}}\right)^{\prime} \Lambda_{Z}\left(\theta-\theta_{0} \iota_{K_{1}}\right)\right)\right) \\
& \pi_{0}\left(b, \tau \mid h_{0}\right)=\left(\frac{\tau h_{0}}{2 \pi}\right)^{\frac{K_{2}}{2}} \tau^{-1}\left|\Lambda_{W}\right|^{1 / 2} \exp \left(-\frac{\tau h_{0}}{2}\left(b-b_{0} \iota_{K_{2}}\right)^{\prime} \Lambda_{W}\left(b-b_{0} \iota_{K_{2}}\right)\right)
\end{aligned}
$$

Solving these equations is considerably easier than solving the equivalent expression in the one-step approach.

### 2.3.1. The first step of the robust Bayesian estimator

Let $y^{*}=y-W b$. Combining the pdf of $y^{*}$ and the pdf of the base prior, we get the predictive density corresponding to the base prior ${ }^{6}$ :

$$
\begin{align*}
m\left(y^{*} \mid \pi_{0}, b, g_{0}\right) & =\int_{0}^{\infty} \int_{\mathbb{R}^{K_{1}}} \pi_{0}\left(\theta, \tau \mid g_{0}\right) \times p\left(y^{*} \mid Z, b, \tau\right) d \theta d \tau  \tag{11}\\
& =\widetilde{H}\left(\frac{g_{0}}{g_{0}+1}\right)^{K_{1} / 2}\left(1+\left(\frac{g_{0}}{g_{0}+1}\right)\left(\frac{R_{\theta_{0}}^{2}}{1-R_{\theta_{0}}^{2}}\right)\right)^{-\frac{N(T-1)}{2}}
\end{align*}
$$

with $\widetilde{H}=\frac{\Gamma\left(\frac{N(T-1)}{2}\right)}{\pi\left(\frac{N(T-1)}{2}\right)_{v(b)}\left(\frac{N(T-1)}{2}\right)}, R_{\theta_{0}}^{2}=\frac{\left(\widehat{\theta}(b)-\theta_{0} \iota_{K_{1}}\right)^{\prime} \Lambda_{Z}\left(\widehat{\theta}(b)-\theta_{0} \iota_{K_{1}}\right)}{\left(\widehat{\theta}(b)-\theta_{0} \iota_{K_{1}}\right)^{\prime} \Lambda_{Z}\left(\widehat{\theta}(b)-\theta_{0} \iota_{K_{1}}\right)+v(b)}, \widehat{\theta}(b)=\Lambda_{Z}^{-1} Z^{\prime} y^{*}$ and $v(b)=$ $\left(y^{*}-Z \widehat{\theta}(b)\right)^{\prime}\left(y^{*}-Z \widehat{\theta}(b)\right)$, and where $\Gamma(\cdot)$ is the Gamma function.

Likewise, we can obtain the predictive density corresponding to the contaminated prior for the distribution $q\left(\theta, \tau \mid g_{0}, h_{0}\right) \in Q$ from the class $Q$ of possible contamination distributions:

$$
\begin{equation*}
m\left(y^{*} \mid q, b, g_{0}\right)=\widetilde{H}\left(\frac{g_{q}}{g_{q}+1}\right)^{\frac{K_{1}}{2}}\left(1+\left(\frac{g_{q}}{g_{q}+1}\right)\left(\frac{R_{\theta_{q}}^{2}}{1-R_{\theta_{q}}^{2}}\right)\right)^{-\frac{N(T-1)}{2}} \tag{12}
\end{equation*}
$$

where

$$
R_{\theta_{q}}^{2}=\frac{\left(\widehat{\theta}(b)-\theta_{q} \iota_{K_{1}}\right)^{\prime} \Lambda_{Z}\left(\widehat{\theta}(b)-\theta_{q} \iota_{K_{1}}\right)}{\left(\widehat{\theta}(b)-\theta_{q} \iota_{K_{1}}\right)^{\prime} \Lambda_{Z}\left(\widehat{\theta}(b)-\theta_{q} \iota_{K_{1}}\right)+v(b)}
$$

As the $\varepsilon$-contamination of the prior distributions for $(\theta, \tau)$ is defined by $\pi\left(\theta, \tau \mid g_{0}\right)=(1-\varepsilon) \pi_{0}\left(\theta, \tau \mid g_{0}\right)+$ $\varepsilon q\left(\theta, \tau \mid g_{0}\right)$, the corresponding predictive density is given by:

$$
m\left(y^{*} \mid \pi, b, g_{0}\right)=(1-\varepsilon) m\left(y^{*} \mid \pi_{0}, b, g_{0}\right)+\varepsilon m\left(y^{*} \mid q, b, g_{0}\right)
$$

and

$$
\sup _{\pi \in \Gamma} m\left(y^{*} \mid \pi, b, g_{0}\right)=(1-\varepsilon) m\left(y^{*} \mid \pi_{0}, b, g_{0}\right)+\varepsilon \sup _{q \in Q} m\left(y^{*} \mid q, b, g_{0}\right)
$$

The maximization of $m\left(y^{*} \mid \pi, b, g_{0}\right)$ requires the maximization of $m\left(y^{*} \mid q, b, g_{0}\right)$ with respect to $\theta_{q}$ and $g_{q}$. The first-order conditions lead to

$$
\begin{equation*}
\widehat{\theta}_{q}=\left(\iota_{K_{1}}^{\prime} \Lambda_{Z} \iota_{K_{1}}\right)^{-1} \iota_{K_{1}}^{\prime} \Lambda_{Z} \widehat{\theta}(b) \tag{13}
\end{equation*}
$$

and

$$
\begin{equation*}
\widehat{g}_{q}=\min \left(g_{0}, g^{*}\right) \text { with } g^{*}=\max \left[\left(\frac{\left(N(T-1)-K_{1}\right)}{K_{1}}\left(\frac{R_{\widehat{\theta}_{q}}^{2}}{1-R_{\widehat{\theta}_{q}}^{2}}\right)-1\right)^{-1}, 0\right] \tag{14}
\end{equation*}
$$

Denote $\sup _{q \in Q} m\left(y^{*} \mid q, b, g_{0}\right)=m\left(y^{*} \mid \widehat{q}, b, g_{0}\right)$. Then

$$
m\left(y^{*} \mid \widehat{q}, b, g_{0}\right)=\widetilde{H}\left(\frac{\widehat{g}_{q}}{\widehat{g}_{q}+1}\right)^{\frac{K_{1}}{2}}\left(1+\left(\frac{\widehat{g}_{q}}{\widehat{g}_{q}+1}\right)\left(\frac{R_{\widehat{\theta}_{q}}^{2}}{1-R_{\widehat{\theta}_{q}}^{2}}\right)\right)^{-\frac{N(T-1)}{2}}
$$

[^3]Let $\pi_{0}^{*}\left(\theta, \tau \mid g_{0}\right)$ denote the posterior density of $(\theta, \tau)$ based upon the prior $\pi_{0}\left(\theta, \tau \mid g_{0}\right)$. Also, let $q^{*}\left(\theta, \tau \mid g_{0}\right)$ denote the posterior density of $(\theta, \tau)$ based upon the prior $q\left(\theta, \tau \mid g_{0}\right)$. The ML-II posterior density of $\theta$ is thus given by:

$$
\begin{align*}
\widehat{\pi}^{*}\left(\theta \mid g_{0}\right) & =\int_{0}^{\infty} \widehat{\pi}^{*}\left(\theta, \tau \mid g_{0}\right) d \tau=\widehat{\lambda}_{\theta, g_{0}} \int_{0}^{\infty} \pi_{0}^{*}\left(\theta, \tau \mid g_{0}\right) d \tau+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \int_{0}^{\infty} q^{*}\left(\theta, \tau \mid g_{0}\right) d \tau \\
& =\widehat{\lambda}_{\theta, g_{0}} \pi_{0}^{*}\left(\theta \mid g_{0}\right)+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \widehat{q}^{*}\left(\theta \mid g_{0}\right) \tag{15}
\end{align*}
$$

with

$$
\widehat{\lambda}_{\theta, g_{0}}=\left[1+\frac{\varepsilon}{1-\varepsilon}\left(\frac{\frac{\widehat{g}_{q}}{g_{q}+1}}{\frac{g_{0}}{g_{0}+1}}\right)^{K_{1} / 2}\left(\frac{1+\left(\frac{g_{0}}{g_{0}+1}\right)\left(\frac{R_{\theta_{0}}^{2}}{1-R_{\theta_{0}}^{2}}\right)}{1+\left(\frac{\widehat{g}_{q}}{\hat{g}_{q}+1}\right)\left(\frac{R_{\theta_{q}}^{2}}{1-R_{\hat{\theta}_{q}}^{2}}\right)}\right)^{\frac{N(T-1)}{2}}\right]^{-1} .
$$

Note that $\widehat{\lambda}_{\theta, g_{0}}$ depends upon the ratio of the $R_{\theta_{0}}^{2}$ and $R_{\theta_{q}}^{2}$, but primarily on the sample size $N(T-1)$. Indeed, $\widehat{\lambda}_{\theta, g_{0}}$ tends to 0 when $R_{\theta_{0}}^{2}>R_{\theta_{q}}^{2}$ and tends to 1 when $R_{\theta_{0}}^{2}<R_{\theta_{q}}^{2}$, irrespective of the model fit (i.e, the absolute values of $R_{\theta_{0}}^{2}$ or $R_{\theta_{q}}^{2}$ ). Only the relative values of $R_{\theta_{q}}^{2}$ and $R_{\theta_{0}}^{2}$ matter.

It can be shown that $\pi_{0}^{*}\left(\theta \mid g_{0}\right)$ is the pdf (see the supplementary appendix of Baltagi et al. (2018)) of a multivariate $t$-distribution with mean vector $\theta_{*}\left(b \mid g_{0}\right)$, variance-covariance matrix $\left(\frac{\xi_{0, \theta} M_{0, \theta}^{-1}}{N(T-1)-2}\right)$ and degrees of freedom $(N(T-1))$ with

$$
\begin{equation*}
M_{0, \theta}=\frac{\left(g_{0}+1\right)}{v(b)} \Lambda_{Z} \text { and } \xi_{0, \theta}=1+\left(\frac{g_{0}}{g_{0}+1}\right)\left(\frac{R_{\theta_{0}}^{2}}{1-R_{\theta_{0}}^{2}}\right) \tag{16}
\end{equation*}
$$

$\theta_{*}\left(b \mid g_{0}\right)$ is the Bayes estimate of $\theta$ for the prior distribution $\pi_{0}(\theta, \tau)$ :

$$
\begin{equation*}
\theta_{*}\left(b \mid g_{0}\right)=\frac{\widehat{\theta}(b)+g_{0} \theta_{0} \iota_{K_{1}}}{g_{0}+1} \tag{17}
\end{equation*}
$$

Likewise $\widehat{q}^{*}(\theta)$ is the pdf of a multivariate $t$-distribution with mean vector $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$, variancecovariance matrix $\left(\frac{\xi_{q, \theta} M_{q, \theta}^{-1}}{N(T-1)-2}\right)$ and degrees of freedom $(N(T-1))$ with

$$
\begin{equation*}
\xi_{q, \theta}=1+\left(\frac{\widehat{g}_{q}}{\widehat{g}_{q}+1}\right)\left(\frac{R_{\widehat{\theta}_{q}}^{2}}{1-R_{\widehat{\theta}_{q}}^{2}}\right) \text { and } M_{q, \theta}=\left(\frac{\left(\widehat{g}_{q}+1\right)}{v(b)}\right) \Lambda_{Z} \tag{18}
\end{equation*}
$$

where $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$ is the empirical Bayes estimator of $\theta$ for the contaminated prior distribution $q(\theta, \tau)$ given by:

$$
\begin{equation*}
\widehat{\theta}_{E B}\left(b \mid g_{0}\right)=\frac{\widehat{\theta}(b)+\widehat{g}_{q} \widehat{\theta}_{q} \iota_{K_{1}}}{\widehat{g}_{q}+1} . \tag{19}
\end{equation*}
$$

The mean of the ML-II posterior density of $\theta$ is then:

$$
\begin{align*}
\widehat{\theta}_{M L-I I} & =E\left[\widehat{\pi}^{*}\left(\theta \mid g_{0}\right)\right]  \tag{20}\\
& =\widehat{\lambda}_{\theta, g_{0}} E\left[\pi_{0}^{*}\left(\theta \mid g_{0}\right)\right]+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) E\left[\widehat{q}^{*}\left(\theta \mid g_{0}\right)\right] \\
& =\widehat{\lambda}_{\theta, g_{0}} \theta_{*}\left(b \mid g_{0}\right)+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \widehat{\theta}_{E B}\left(b \mid g_{0}\right)
\end{align*}
$$

The ML-II posterior density of $\theta$, given $b$ and $g_{0}$ is a shrinkage estimator. It is a weighted average of the Bayes estimator $\theta_{*}\left(b \mid g_{0}\right)$ under base prior $g_{0}$ and the data-dependent empirical Bayes estimator $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$. If the base prior is consistent with the data, the weight $\hat{\lambda}_{\theta, g_{0}} \rightarrow 1$ and the ML-II posterior density of $\theta$ gives more weight to the posterior $\pi_{0}^{*}\left(\theta \mid g_{0}\right)$ derived from the elicited prior. In this case $\widehat{\theta}_{M L-I I}$ is close to the Bayes estimator $\theta_{*}\left(b \mid g_{0}\right)$. Conversely, if the base prior is not consistent with the data, the weight $\widehat{\lambda}_{\theta, g_{0}} \rightarrow 0$ and the ML-II posterior density of $\theta$ is then close to the posterior $\widehat{q}^{*}\left(\theta \mid g_{0}\right)$ and to the empirical Bayes estimator $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$. The ability of the $\varepsilon$ contamination model to extract more information from the data is what makes it superior to the classical Bayes estimator based on a single base prior. ${ }^{7}$

### 2.3.2. The second step of the robust Bayesian estimator

Let $\widetilde{y}=y-Z \theta$. Moving along the lines of the first step, the ML-II posterior density of $b$ is given by:

$$
\widehat{\pi}^{*}\left(b \mid h_{0}\right)=\widehat{\lambda}_{b, h_{0}} \pi_{0}^{*}\left(b \mid h_{0}\right)+\left(1-\widehat{\lambda}_{b, h_{0}}\right) \widehat{q}^{*}\left(b \mid h_{0}\right)
$$

with

$$
\widehat{\lambda}_{b, h_{0}}=\left[1+\frac{\varepsilon}{1-\varepsilon}\left(\frac{\frac{\widehat{h}}{\widehat{h}+1}}{\frac{h_{0}}{h_{0}+1}}\right)^{K_{2} / 2}\left(\frac{1+\left(\frac{h_{0}}{h_{0}+1}\right)\left(\frac{R_{b_{0}}^{2}}{1-R_{b_{0}}^{2}}\right)}{1+\left(\frac{\widehat{h}}{\widehat{h}+1}\right)\left(\frac{R_{\hat{b}_{q}}^{2}}{1-R_{\hat{b}_{q}}^{2}}\right)}\right)^{\frac{N(T-1)}{2}}\right]^{-1}
$$

and where $\widehat{\lambda}_{b, h_{0}}$ is defined in a similar manner as $\hat{\lambda}_{\theta, g_{0}}{ }^{8} \pi_{0}^{*}\left(b \mid h_{0}\right)$ is the pdf of a multivariate $t$-distribution with mean vector $b_{*}\left(\theta \mid h_{0}\right)$, variance-covariance matrix $\left(\frac{\xi_{0, b} M_{0, b}^{-1}}{N(T-1)-2}\right)$ and degrees of freedom $(N(T-1))$ with

$$
M_{0, b}=\frac{\left(h_{0}+1\right)}{v(\theta)} \Lambda_{W} \text { and } \xi_{0, b}=1+\left(\frac{h_{0}}{h_{0}+1}\right) \frac{\left(\widehat{b}(\theta)-b_{0} \iota_{K_{2}}\right)^{\prime} \Lambda_{W}\left(\widehat{b}(\theta)-b_{0} \iota_{K_{2}}\right)}{v(\theta)}
$$

$b_{*}\left(\theta \mid h_{0}\right)$ is the Bayes estimate of $b$ for the prior distribution $\pi_{0}\left(b, \tau \mid h_{0}\right)$ :

$$
b_{*}\left(\theta \mid h_{0}\right)=\frac{\widehat{b}(\theta)+h_{0} b_{0} \iota_{K_{2}}}{h_{0}+1}
$$

[^4]$q^{*}\left(b \mid h_{0}\right)$ is the pdf of a multivariate $t$-distribution with mean vector $\widehat{b}_{E B}\left(\theta \mid h_{0}\right)$, variance-covariance matrix $\left(\frac{\xi_{1, b} M_{1, b}^{-1}}{N(T-1)-2}\right)$ and degrees of freedom $(N(T-1))$ with
$$
\xi_{1, b}=1+\left(\frac{\widehat{h}_{q}}{\widehat{h}_{q}+1}\right) \frac{\left(\widehat{b}(\theta)-\widehat{b}_{q} \iota_{K_{2}}\right)^{\prime} \Lambda_{W}\left(\widehat{b}(\theta)-\widehat{b}_{q} \iota_{K_{2}}\right)}{v(\theta)} \text { and } M_{1, b}=\left(\frac{\widehat{h}+1}{v(\theta)}\right) \Lambda_{W}
$$
$\widehat{b}_{E B}\left(\theta \mid h_{0}\right)$ is the empirical Bayes estimator of $b$ for the contaminated prior distribution $q\left(b, \tau \mid h_{0}\right)$ :
$$
\widehat{b}_{E B}\left(\theta \mid h_{0}\right)=\frac{\widehat{\theta}(b)+\widehat{h}_{q} \widehat{b}_{q} \iota_{K_{2}}}{\widehat{h}_{q}+1}
$$

The mean of the ML-II posterior density of $b$ is hence given by:

$$
\begin{equation*}
\widehat{b}_{M L-I I}=\widehat{\lambda}_{b} b_{*}\left(\theta \mid h_{0}\right)+\left(1-\widehat{\lambda}_{\theta}\right) \widehat{b}_{E B}\left(\theta \mid h_{0}\right) \tag{21}
\end{equation*}
$$

The ML-II posterior variance-covariance matrix of $b$ can be derived in a similar fashion ${ }^{9}$ to that of $\hat{\theta}_{M L-I I}$.

### 2.4. Estimating the ML-II posterior variance-covariance matrix

Many have raised concerns about the unbiasedness of the posterior variance-covariance matrices of $\widehat{\theta}_{M L-I I}$ and $\widehat{b}_{M L-I I}$. Indeed, they will both be biased towards zero as $\widehat{\lambda}_{\theta, g_{0}}$ and $\widehat{\lambda}_{b, h_{0}} \rightarrow 0$ and converge to the empirical variance which is known to underestimate the true variance (see e.g. Berger and Berliner (1986); Gilks et al. (1997); Robert (2007)). Consequently, the assessment of the performance of either $\widehat{\theta}_{M L-I I}$ or $\widehat{b}_{M L-I I}$ using standard quadratic loss functions can not be conducted using the analytical expressions. What is needed is an unbiased estimator of the true ML-II variances. Baltagi et al. (2018) proposed two different strategies to approximate these, each with different desirable properties: MCMC with multivariate $t$-distributions or block resampling bootstrap. Simulations show that one needs as few as 20 bootstrap samples to achieve acceptable results ${ }^{10}$. Here, we will use the same individual block resampling bootstrap method. Following Kapetanios (2008), individual block resampling consists of drawing an $(N \times(T-1))$ matrix $Y^{B R}$ whose rows are obtained by resampling those of an $(N \times(T-1))$ matrix $Y$ with replacement. Conditionally on $Y$, the rows of $Y^{B R}$ are independent and identically distributed. The following algorithm is used to approximate the variance matrices:

1. Loop over $B R$ samples
2. In the first step, compute the mean of the ML-II posterior density of $\theta$ using our initial shrinkage procedure

$$
\begin{aligned}
\widehat{\theta}_{M L-I I, b r} & =E\left[\widehat{\pi}^{*}\left(\theta \mid g_{0}\right)\right] \\
& =\widehat{\lambda}_{\theta, g_{0}} \theta_{*}\left(b \mid g_{0}\right)+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \widehat{\theta}_{E B}\left(b \mid g_{0}\right) .
\end{aligned}
$$

[^5]3. In the second step, compute the mean of the ML-II posterior density of $b$ :
$$
\widehat{b}_{M L-I I, b r}=\widehat{\lambda}_{b} b_{*}\left(\theta \mid h_{0}\right)+\left(1-\widehat{\lambda}_{\theta}\right) \widehat{b}_{E B}\left(\theta \mid h_{0}\right)
$$
4. Once the $B R$ bootstraps are completed, use the $\left(K_{1} \times B R\right)$ matrix of coefficients $\theta^{(B R)}$ and the $(N \times B R)$ matrix of coefficients $b^{(B R)}$ to compute:
\[

$$
\begin{array}{ll}
\widehat{\theta}_{M L-I I}=E\left[\theta^{(B R)}\right], & \widehat{\sigma}_{\theta_{M L-I I}}=\sqrt{\operatorname{diag}\left(\operatorname{Var}\left[\theta^{(B R)}\right]\right)} \\
\widehat{b}_{M L-I I}=E\left[b^{(B R)}\right], & \widehat{\sigma}_{b_{M L-I I}}=\sqrt{\operatorname{diag}\left(\operatorname{Var}\left[b^{(B R)}\right]\right)}
\end{array}
$$
\]

## 3. Monte Carlo simulation study

In what follows, we compare the finite sample properties of our proposed estimator with those of standard classical estimators.

### 3.1. The DGP of the Monte Carlo simulation study

For the random effects (RE), the Chamberlain (1982)-type fixed effects (FE) world and the Hausman and Taylor (1981) (HT) worlds, we use the same DGP as that of Baltagi et al. (2018) extended to the dynamic case. For the dynamic homogeneous/heterogeneous panel data model with common trends or with common correlated effects, we are inspired by Chudik and Pesaran (2015a,b).

$$
\begin{align*}
& y_{i t}=\rho y_{i, t-1}+x_{1,1, i t} \beta_{1,1}+x_{1,2, i t} \beta_{1,2}+x_{2, i t} \beta_{2}+V_{1, i} \eta_{1}+V_{2, i} \eta_{2}+\mu_{i}+u_{i t},  \tag{22}\\
& \text { for } i=1, \ldots, N, t=2, \ldots, T, \text { with } \\
& x_{1,1, i t}=0.7 x_{1,1, i t-1}+\delta_{i}+\zeta_{i t} \\
& x_{1,2, i t}=0.7 x_{1,2, i t-1}+\theta_{i}+\varsigma_{i t} \\
& u_{i t} \sim N\left(0, \tau^{-1}\right),\left(\delta_{i}, \theta_{i}, \zeta_{i t}, \varsigma_{i t}\right) \sim U(-6,6) \\
& \text { and } \rho=0.75, \beta_{1,1}=\beta_{1,2}=\beta_{2}=1 .
\end{align*}
$$

1. For a random effects (RE) world, we assume that:

$$
\begin{aligned}
\eta_{1} & =\eta_{2}=0 \\
x_{2, i t} & =0.7 x_{2, i t-1}+\kappa_{i}+\vartheta_{i t},\left(\kappa_{i}, \vartheta_{i t}\right) \sim U(-6,6) \\
\mu_{i} & \sim N\left(0, \sigma_{\mu}^{2}\right), \sigma_{\mu}^{2}=4 \tau^{-1}
\end{aligned}
$$

Furthermore, $x_{1,1, i t}, x_{1,2, i t}$ and $x_{2, i t}$ are assumed to be exogenous in that they are not correlated with $\mu_{i}$ and $u_{i t}$.
2. For a Chamberlain-type fixed effects (FE) world, we assume that:

$$
\begin{aligned}
\eta_{1} & =\eta_{2}=0 \\
x_{2, i t} & =\delta_{2, i}+\omega_{2, i t}, \delta_{2, i} \sim N\left(m_{\delta_{2}}, \sigma_{\delta_{2}}^{2}\right), \omega_{2, i t} \sim N\left(m_{\omega_{2}}, \sigma_{\omega_{2}}^{2}\right) \\
m_{\delta_{2}} & =m_{\omega_{2}}=1, \sigma_{\delta_{2}}^{2}=8, \sigma_{\omega_{2}}^{2}=2 \\
\mu_{i} & =x_{2, i 1} \pi_{1}+x_{2, i 2} \pi_{2}+\ldots+x_{2, i T} \pi_{T}+\nu_{i}, \nu_{i} \sim N\left(0, \sigma_{\nu}^{2}\right) \\
\sigma_{\nu}^{2} & =1, \pi_{t}=(0.8)^{T-t} \text { for } t=1, \ldots, T
\end{aligned}
$$

$x_{1,1, i t}$ and $x_{1,2, i t}$ are assumed to be exogenous but $x_{2, i t}$ is correlated with the $\mu_{i}$ and we assume an exponential growth for the correlation coefficient $\pi_{t}$.
3. For a Hausman-Taylor (HT) world, we assume that:

$$
\begin{aligned}
\eta_{1} & =\eta_{2}=1 \\
x_{2, i t} & =0.7 x_{2, i t-1}+\mu_{i}+\vartheta_{i t}, \vartheta_{i t} \sim U(-6,6) \\
V_{1, i} & =1, \forall i \\
V_{2, i} & =\mu_{i}+\delta_{i}+\theta_{i}+\xi_{i}, \xi_{i} \sim U(-6,6) \\
\mu_{i} & \sim N\left(0, \sigma_{\mu}^{2}\right) \text { and } \sigma_{\mu}^{2}=4 \tau^{-1}
\end{aligned}
$$

$x_{1,1, i t}$ and $x_{1,2, i t}$ and $V_{1, i}$ are assumed to be exogenous while $x_{2, i t}$ and $V_{2, i}$ are endogenous because they are correlated with the $\mu_{i}$ but not with the $u_{i t}$.
4. For the homogeneous panel data world with common trends, we follow Chudik and Pesaran (2015a,b) and assume that

$$
\begin{equation*}
y_{i t}=\rho y_{i, t-1}+x_{i t} \beta_{1}+x_{i, t-1} \beta_{2}+f_{t}^{\prime} \gamma_{i}+u_{i t}, \text { for } i=1, \ldots, N, t=2, \ldots, T \tag{23}
\end{equation*}
$$

with

$$
\begin{aligned}
x_{i t} & =\alpha_{x_{i}} y_{i, t-1}+f_{t}^{\prime} \gamma_{x_{i}}+\omega_{x_{i t}} \\
\omega_{x_{i t}} & =\varrho_{x_{i}} \omega_{x_{i t-1}}+\zeta_{x_{i t}} \\
\gamma_{i l} & =\gamma_{l}+\eta_{i, \gamma_{l}}, \text { for } l=1, \ldots, m \\
\gamma_{x_{i l}} & =\gamma_{x_{l}}+\eta_{i, \gamma_{x_{l}}}, \text { for } l=1, \ldots, m
\end{aligned}
$$

where

$$
\begin{array}{ccl}
\zeta_{x_{i t}} \sim U(-3,3), & \eta_{i, \gamma_{l}} \sim N\left(0, \sigma_{\gamma_{l}}^{2}\right), & \eta_{i, \gamma_{x_{l}}} \sim N\left(0, \sigma_{\gamma_{x_{l}}}^{2}\right) \\
\sigma_{\gamma_{l}}^{2}=\sigma_{\gamma_{x_{l}}}^{2}=0.2^{2}, & \gamma_{l}=\sqrt{l \times c_{\gamma}}, & \gamma_{x_{l}}=\sqrt{l \times c_{x, l}} \\
c_{\gamma}=(1 / m)-\sigma_{\gamma_{l}}^{2}, & c_{x, l}=\frac{2}{m(m+1)}-\frac{2 \sigma_{\gamma_{x_{l}}}^{2}}{(m+1)}, & \text { and } u_{i t} \sim N\left(0, \tau^{-1}\right) .
\end{array}
$$

$f_{t}$ and $\gamma_{i}$ are $(m \times 1)$ vectors. We consider $m=2$ deterministic known common trends: one linear trend $f_{t, 1}=t / T$ and one polynomial trend: $f_{t, 2}=t / T+1.4(t / T)^{2}-3(t / T)^{3}$ for $t=1, \ldots, T$. The feedback coefficients follow a uniform distribution $\alpha_{x_{i}} \sim U(0,0.15)$ and are non-zero for all $i\left(\alpha_{x_{i}} \neq 0\right)$. They lead to weakly exogenous regressors $x_{i t}$.
5. For the homogeneous panel data world with common correlated effects, we follow Chudik and Pesaran (2015a,b), and assume that the $m$ common trends $f_{t}$ in (23), are replaced with unobserved common factors:

$$
f_{t l}=\rho_{f l} f_{t-1, l}+\xi_{f t l}, \xi_{f t l} \sim N\left(0,1-\rho_{f l}^{2}\right), l=1, \ldots, m
$$

We assume that the common factors are independent stationary $A R(1)$ processes with $\rho_{f l}=$ 0.6 for $l=1, \ldots, m$.
6. For the heterogeneous panel data world with common correlated effects, we follow Chudik and Pesaran (2015a,b) and assume that $\rho$ (resp. $\beta_{1}$ ) in the model (23) is replaced by individual coefficients $\rho_{i} \sim U(0.6,0.9)$ (resp. $\beta_{1 i} \sim U(0.5,1)$ ) for $i=1, \ldots, N$ and we keep the $m$ unobserved common factors as defined previously.

For each set-up, we vary the size of the sample and the length of the panel. We choose several $(N, T)$ pairs with $N=100,200$ and $T=10,30$ for cases 1 to 3 and $N=(50,100)$ and $T=(30,50)$ for cases 4 to 6 . The autoregressive coefficient is set as $\rho=0.75$. We set the initial values of $y_{i t}$, $x_{1,1, i t}, x_{1,2, i t}$ and $x_{2, i t}, x_{i t}$ to zero. We next generate all the $x_{1,1, i t}, x_{1,2, i t}, x_{1,2, i t}, x_{i t}, y_{i t}, u_{i t}, \zeta_{i t}$, $\varsigma_{i t}, \omega_{2, i t}, \ldots$ over $T+T_{0}$ time periods and we drop the first $T_{0}(=50)$ observations to reduce the dependence on the initial values. The robust Bayesian estimators for the two-stage hierarchy are estimated with $\varepsilon=0.5$, though we investigate the robustness of our results to various values of $\varepsilon .{ }^{11}$

We must set the hyperparameters values $\theta_{0}, b_{0}, g_{0}, h_{0}, \tau$ for the initial distributions of $\theta \sim$ $N\left(\theta_{0} \iota_{K_{1}},\left(\tau g_{0} \Lambda_{Z}\right)^{-1}\right)$ and $b \sim N\left(b_{0} \iota_{K_{2}},\left(\tau h_{0} \Lambda_{W}\right)^{-1}\right)$ where $\theta=\left[\rho, \beta_{1,1}, \beta_{1,2}, \beta_{2}\right]^{\prime}$ for the first three cases and $\theta=\left[\rho, \beta_{1}, \beta_{2}\right]^{\prime}$ for the last three cases. While we can choose arbitrary values for $\theta_{0}, b_{0}$ and $\tau$, the literature generally recommends using the unit information prior (UIP) to set the $g$-priors. ${ }^{12}$ In the normal regression case, and following Kass and Wasserman (1995), the UIP corresponds to $g_{0}=h_{0}=1 / N(T-1)$, leading to Bayes factors that behave like the Bayesian Information Criterion (BIC).

For the 2 S robust estimators, we use $B R=20$ samples in the block resampling bootstrap. For each experiment, we run $R=1,000$ replications and we compute the means, standard errors and root mean squared errors (RMSEs) of the coefficients and the residual variances.

### 3.1.1. The random effects world

Rewrite the general dynamic model (8) as follows:

$$
\begin{aligned}
y= & Z \theta+W b+u=Z \theta+Z_{\mu} \mu+u \\
& \quad \text { with } Z_{i t}^{\prime}=\left[y_{i t-1}, X_{i t}^{\prime}\right], \theta=\left[\rho, \beta^{\prime}\right]^{\prime} \text { and } X_{i t}^{\prime}=\left[x_{1,1, i t}, x_{1,2, i t}, x_{2, i t}\right]
\end{aligned}
$$

where $u \sim N(0, \Sigma), \Sigma=\tau^{-1} I_{N(T-1)}, Z_{\mu}=I_{N} \otimes \iota_{T-1}$ is $(N(T-1) \times N), \otimes$ is the Kronecker product, $\iota_{T-1}$ is a $(T-1 \times 1)$ vector of ones and $\mu(\equiv b)$ is a $(N \times 1)$ vector of idiosyncratic parameters. When $W \equiv Z_{\mu}$, the random effects, $\mu \sim N\left(0, \sigma_{\mu}^{2} I_{N}\right)$, are associated with the error term $\nu=Z_{\mu} \mu+u$ with $\operatorname{Var}(\nu)=\sigma_{\mu}^{2}\left(I_{N} \otimes J_{T-1}\right)+\sigma_{u}^{2} I_{N(T-1)}$, where $J_{T-1}=\iota_{T-1} \iota_{T-1}^{\prime}$. This model is usually estimated using GMM. It could also be estimated using the quasi-maximum likelihood (QML) estimator (see Kripfganz (2016), Bun et al. (2017), Moral-Benito et al. (2019)). Thus we compare our Bayesian two-stage estimator with the Arellano-Bond GMM and the QML estimators. ${ }^{13}$

Table 1 reports the results of fitting the Bayesian two-stage model with block resampling bootstrap ( $2 S$ bootstrap) ${ }^{14}$ along with those from the GMM and QMLE, each in a separate panel for

[^6]$N=100, T=10$ (see Table B. 1 in the supplementary material for $N=200, T=30$ ). ${ }^{15}$ The true parameter values appear in the first row of the Table. The last column reports the computation time in seconds. ${ }^{16}$ Note that the computation time increases significantly as we move from a small sample to a larger one (the QMLE being the fastest).

The first noteworthy feature of the Table is that all the estimators yield parameter estimates, standard errors ${ }^{17}$ and RMSEs that are very close. For the coefficient of the lagged dependent variable, $\rho$, as well as for the $\beta$ coefficients, the RMSE are the lowest both for the $2 S$ bootstrap and the QMLE when $N=100$ and $T=10$ or when $N=200$ and $T=30$. GMM yields higher RMSEs for all coefficients. The $2 S$ bootstrap and the QMLE have also better RMSEs than the GMM estimator for the residual disturbances $\left(\sigma_{u}^{2}\right)$ and the random effects $\left(\sigma_{\mu}^{2}\right)$. Table 1 confirms that the base prior is not consistent with the data since $\hat{\lambda}_{\theta, g_{0}}$ is close to zero. The ML-II posterior density of $\theta$ is close to the posterior $\widehat{q}^{*}\left(\theta \mid g_{0}\right)$ and to the empirical Bayes estimator $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$. In contrast, $\widehat{\lambda}_{\mu}$ is close to 0.5 so the Bayes estimator $b_{*}\left(\theta \mid h_{0}\right)$ under the base prior $h_{0}$ and the empirical Bayes estimator $\widehat{b}_{E B}\left(\theta \mid h_{0}\right)$ each contribute similarly to the random effects $b_{i}\left(\equiv \mu_{i}\right)$. Note that the computation times are roughly the same for the $2 S$ bootstrap and QMLE compared to those of GMMs which explode when $N$ and $T$ increase.

We can also use a simple and efficient way to drastically reduce the computation time of our Bayesian two-stage estimator. The ML-II posterior density of $\theta$ in (15) is a two-component finite mixture of multivariate $t$-distributions whose location parameters and scale matrices are given in (16) to (19). Following McLachlan and Lee (2013), one can generate mixture of multivariate skewed (or non-skewed) $t$-distributions via an EM Algorithm approach. Thus, generating 1000 (or more) random samples of $K_{1}$-dimensional multivariate $t$ observations with location parameters, scale matrices given in (16)-(19) and degrees of freedom $N(T-1)$, allows one to sample a mixture of the two components to get 1000 (or more) random vectors of $\theta_{M L-I I}$. The latter can then be used to compute the variances of the $K_{1}$ parameters. ${ }^{18}$ Using this device reduces the computation time by as much as by $80-90 \%$ in all cases, although small discrepancies with the bootstrapped standard errors may occur in specific cases. For instance, for $N=100, T=10$ (resp. $N=200$, $T=30$ ) and $r=0.8$, the computation time shrinks from 285 seconds to 19 seconds (resp. 3079 seconds to 289 seconds) - a reduction by a factor of 15 (resp. 10.6) - and the estimated standard errors of the parameters $\rho$ and $\beta$ by the bootstrap and mixture approaches differ by at most 0.007 (resp. 0.003). (see Tables C. 1 to C. 3 in the supplementary material). This considerable time-saving device makes our Bayesian two-stage estimator all the more favorable.

Table B. 2 in the supplementary material gives the results when the coefficient $\rho$ of the lagged dependent variable is increased from 0.75 to 0.98 (close to the unit root) for $N=100$ and $T=10$. The GMM estimator performs the worst as compared to the two other estimators, mainly for the estimation of the residual disturbances $\left(\sigma_{u}^{2}\right)$ and the random effects $\left(\sigma_{\mu}^{2}\right)$. An important point to

[^7]note is the significant bias and unlikely estimated values of $\sigma_{u}^{2}$ and $\sigma_{\mu}^{2}$ for QMLE. ${ }^{19}$ 2S bootstrap has the lowest RMSE for all the parameters and the variances of specific effects and remainder disturbances. Even with a coefficient $\rho$ very close to the unit root, the $95 \%$ Highest Posterior Density Interval (HPDI) of the Bayesian estimator confirm the stationarity of the $A R(1)$ process. It does not therefore seem necessary to impose a stationarity constraint on the prior distribution of $\rho$.

### 3.1.2. The Chamberlain-type fixed effects world

For the Chamberlain (1982)-type specification, the individual effects are given by $\mu=\underline{X} \Pi+$ $\varpi$, where $\underline{X}$ is a $\left(N \times(T-1) K_{x}\right)$ matrix with $\underline{X}_{i}=\left(X_{i 2}^{\prime}, \ldots, X_{i T}^{\prime}\right)$ and $\Pi=\left(\pi_{2}^{\prime}, \ldots, \pi_{T}^{\prime}\right)^{\prime}$ is a $\left((T-1) K_{x} \times 1\right)$ vector. Here $\pi_{t}$ is a $\left(K_{x} \times 1\right)$ vector of parameters to be estimated. The model can be rewritten as: $y=Z \theta+Z_{\mu} \underline{X} \Pi+Z_{\mu} \varpi+u$. We concatenate $\left[Z, Z_{\mu} \underline{X}\right]$ into a single matrix of observables $Z^{*}$ and let $W b \equiv Z_{\mu} \varpi$.

For the Chamberlain world, we compare the QML estimator to our Bayesian estimator. These are based on the transformed model: $y_{i t}=\rho y_{i, t-1}+x_{1,1, i t} \beta_{1,1}+x_{1,2, i t} \beta_{1,2}+x_{2, i t} \beta_{2}+\sum_{t=2}^{T} x_{2, i t} \pi_{t}+$ $\varpi_{i}+u_{i t}$ or $y=Z^{*} \theta^{*}+W b+u=Z^{*} \theta^{*}+Z_{\mu} \varpi+u$ where $Z^{*}=\left[y_{-1}, x_{1,1}, x_{1,2}, x_{2}, x_{2}\right], W=Z_{\mu}$ and $b=\varpi$.

Table 1 once again shows that the results of the $2 S$ bootstrap are very close to those of the QML estimator. Table B. 3 in the supplementary material reports the estimates of the $\pi_{t}$ coefficients. $2 S$ bootstrap has RMSE very close to those of QMLE whatever the sample size except for $\sigma_{\mu}^{2}$ when $N=100$ and $T=10$ but this difference diminishes quickly when $N=200$ and $T=30$ (see Table B. 4 in the supplementary material). Hsiao and Zhou (2018) show that a properly specified QMLE that uses the Chamberlain approach to condition the unobserved effects and initial values on the observed strictly exogenous covariates is asymptotically unbiased if $N$ goes to infinity whether $T$ is fixed or goes to infinity. ${ }^{20}$ Note that the computation times of the QMLE are 1.6 to 3.7 times longer than those of the $2 S$ bootstrap. ${ }^{21}$ Here again, the RMSE of $2 S$ bootstrap and QMLE are close to each other.

[^8]
### 3.1.3. The Hausman-Taylor world

The static Hausman-Taylor model (henceforth HT, see Hausman and Taylor (1981)) posits that $y=X \beta+V \eta+Z_{\mu} \mu+u$, where $V$ is a vector of time-invariant variables, and that subsets of $X$ (e.g., $\left.X_{2, i}^{\prime}\right)$ and $V\left(e . g ., V_{2 i}^{\prime}\right)$ may be correlated with the individual effects $\mu$, but leaves the correlations unspecified. Hausman and Taylor (1981) proposed a two-step IV estimator.

For our dynamic general model (8) and for equation (22): $y=Z \theta+W b+u=\rho y_{-1}+X \beta+$ $V \eta+Z_{\mu} \mu+u$, we assume that $\left(\bar{X}_{2, i}^{\prime}, V_{2 i}^{\prime}\right.$ and $\left.\mu_{i}\right)$ are jointly normally distributed:

$$
\left.\left(\begin{array}{c}
\mu_{i} \\
\bar{X}_{2, i}^{\prime} \\
V_{2 i}^{\prime}
\end{array}\right)\right) \sim N\left(\left(\begin{array}{c}
0 \\
\left.\left.\binom{E_{\bar{X}_{2}^{\prime}}}{E_{V_{2}^{\prime}}}\right),\left(\begin{array}{cc}
\Sigma_{11} & \Sigma_{12} \\
\Sigma_{21} & \Sigma_{22}
\end{array}\right)\right), ~ \text {, }
\end{array}\right.\right.
$$

where $\bar{X}_{2, i}^{\prime}$ is the individual mean of $X_{2, i t}^{\prime}$ and $E_{\bar{X}_{2}^{\prime}}$ is the general mean of $X_{2}^{\prime}$. We could estimate the conditional distribution of $\mu_{i} \mid \bar{X}_{2, i}^{\prime}, V_{2 i}^{\prime}$ if we knew the elements of the variance-covariance matrix $\Sigma_{j s}$. We can nevertheless assume that

$$
\mu_{i}=\left(\bar{X}_{2, i}^{\prime}-E_{\bar{X}_{2}^{\prime}}\right) \theta_{X}+\left(V_{2 i}^{\prime}-E_{V_{2}^{\prime}}\right) \theta_{V}+\varpi_{i}
$$

where $\varpi_{i}$ is uncorrelated with $u_{i t}$, and where $\theta_{X}$ and $\theta_{V}$ are vectors of parameters to be estimated. In order to identify the coefficient vector of $V_{2 i}^{\prime}$ and to avoid possible collinearity problems, we assume that the individual effects are given by:

$$
\begin{equation*}
\mu_{i}=\left(\bar{X}_{2, i}^{\prime}-E_{\bar{X}_{2}^{\prime}}\right) \theta_{X}+f\left[\left(\bar{X}_{2, i}^{\prime}-E_{\bar{X}_{2}^{\prime}}\right) \odot\left(V_{2 i}^{\prime}-E_{V_{2}^{\prime}}\right)\right] \theta_{V}+\varpi_{i} \tag{24}
\end{equation*}
$$

where $\odot$ is the Hadamard product and $f\left[\left(\bar{X}_{2, i}^{\prime}-E_{\bar{X}_{2}^{\prime}}\right) \odot\left(V_{2 i}^{\prime}-E_{V_{2}^{\prime}}\right)\right]$ can be a nonlinear function of $\left(\bar{X}_{2, i}^{\prime}-E_{\overline{X_{2}^{\prime}}}\right) \odot\left(V_{2 i}^{\prime}-E_{V_{2}^{\prime}}\right)$. The first term on the right-hand side of equation (24) corresponds to the Mundlak (1978) transformation while the middle term captures the correlation between $V_{2 i}^{\prime}$ and $\mu_{i}$. The individual effects, $\mu$, are a function of $P X$ and $(f[P X \odot V])$, i.e., a function of the column-by-column Hadamard product of $P X$ and $V$ where $\left.P=\left(I_{N} \otimes J_{T-1}\right) /(T-1)\right)$ is the between transformation. We can once again concatenate $\left[y_{-1}, X, P X, f[P X \odot V]\right.$ ] into a single matrix of observables $Z^{*}$ and let $W b \equiv Z_{\mu} \varpi$.
For our model (22), $y_{i t}=\rho y_{i, t-1}+x_{1,1, i t} \beta_{1,1}+x_{1,2, i t} \beta_{1,2}+x_{2, i t} \beta_{2}+V_{1, i} \eta_{1}+V_{2, i} \eta_{2}+\mu_{i}+u_{i t}$ or $y=\rho y_{-1}+X_{1} \beta_{1}+x_{2} \beta_{2}+V_{1} \eta_{1}+V_{2} \eta_{2}+Z_{\mu} \mu+u$. Then, we assume that

$$
\begin{equation*}
\mu_{i}=\left(\bar{x}_{2, i}-E_{\bar{x}_{2}}\right) \theta_{X}+f\left[\left(\bar{x}_{2, i}-E_{\bar{x}_{2}}\right) \odot\left(V_{2 i}-E_{V_{2}}\right)\right] \theta_{V}+\varpi_{i} . \tag{25}
\end{equation*}
$$

We propose adopting the following strategy: If the correlation between $\mu_{i}$ and $V_{2 i}$ is quite large $(>0.2)$, use $f[]=.\left(\bar{x}_{2, i}-E_{\bar{x}_{2}}\right)^{2} \odot\left(V_{2 i}-E_{V_{2}}\right)^{s}$ with $s=1$. If the correlation is weak, set $s=2$. In real-world applications, we do not know the correlation between $\mu_{i}$ and $V_{2 i}$ a priori. We can use a proxy of $\mu_{i}$ defined by the OLS estimation of $\mu$ : $\widehat{\mu}=\left(Z_{\mu}^{\prime} Z_{\mu}\right)^{-1} Z_{\mu}^{\prime} \widehat{y}$ where $\widehat{y}$ are the fitted values of the pooling regression $y=\rho y_{-1}+X_{1} \beta_{1}+x_{2} \beta_{2}+V_{1} \eta_{1}+V_{2} \eta_{2}+\zeta$. Then, we compute the correlation between $\widehat{\mu}$ and $V_{2}$. In our simulation study, it turns out the correlations between $\mu$ and $V_{2}$ are large: 0.65. Hence, we choose $s=1$. In this specification, $Z=\left[y_{-1}, x_{1,1}, x_{1,2}, x_{2}, V_{1}, V_{2}, P x_{2}, f\left[P x_{2} \odot V_{2}\right]\right], W=Z_{\mu}$ and $b=\varpi$.

Our $2 S$ bootstrap estimation method is compared with the two-stage quasi-maximum likelihood sequential approach proposed by Kripfganz and Schwarz (2019). In the first stage, they estimate the coefficients of the time-varying regressors without relying on coefficient estimates for the timeinvariant regressors using the quasi-maximum likelihood (QML) estimator of Hsiao et al. (2002) with the xtdpdqml Stata command. Subsequently, they regress the first-stage residuals on the time-invariant regressors. They achieve identification by using instrumental variables in the spirit of Hausman and Taylor (1981), and they adjust the second-stage standard errors to account for the first-stage estimation error. ${ }^{22}$ They have proposed a new xtseqreg Stata command which implements the standard error correction for two-stage dynamic linear panel data models. ${ }^{23}$

Table 1 compares results of the $2 S$ bootstrap estimator to those of the two-stage QML sequential approach. Once again, the estimates and the RMSE are very close to one another (see Table B. 5 in the supplementary material for other $(T, N)$ simulations). On the other hand, the $2 S$ bootstrap has a lower RMSE for $\eta_{2}$ (for $N=100$ and $\left.T=10\right)$ and ( $N=100$ and $T=30$ ). This is true despite the fact that the $2 S$ bootstrap estimator yields a slightly upward biased estimate of $\eta_{2}$, the coefficient associated with the time-invariant variable $Z_{2, i}$ which is itself correlated with $\mu_{i}$. This bias decreases as $T$ increases (from $3.9 \%$ for $T=10$ to $1.3 \%$ for $T=30$ ). Interestingly, the standard errors of that same coefficient $\eta_{2}$ are smaller when using the Bayesian estimator as compared to the two-stage QMLE, and especially when $T$ is larger. Even with a slight bias, the $95 \%$ confidence intervals of the Bayesian estimator are narrower and entirely nested within those obtained with the two-stage QML sequential approach. We also reached the same conclusion in a static model (see Baltagi et al. (2018)). Note that the $2 S$ bootstrap estimator yields very small biases of $\sigma_{\mu}^{2}$ but these biases decrease rapidly as the individual span is increased from $-1.5 \%$ for $N=100$ to $-0.75 \%$ for $N=200$. Finally, note that the computation times of the two-stage QML sequential approach are 1.1 to 2.6 times longer than those of the $2 S$ bootstrap. ${ }^{24}$

### 3.1.4. The dynamic homogeneous panel data world with common trends

The dynamic homogeneous panel data world with common trends is defined as:

$$
y_{i t}=\rho y_{i, t-1}+x_{i t} \beta_{1}+x_{i, t-1} \beta_{2}+f_{t}^{\prime} \gamma_{i}+u_{i t}
$$

Since the $m$ common trends, $f_{t}$, are known, we can rewrite the general dynamic model (8) as follows:

$$
\begin{aligned}
y= & Z \theta+W b+u=Z \theta+F \Gamma+u \\
& \quad \text { with } Z_{i t}^{\prime}=\left[y_{i t-1}, X_{i t}^{\prime}\right], \theta=\left[\rho, \beta^{\prime}\right]^{\prime} \text { and } X_{i t}^{\prime}=\left[x_{i, t}, x_{i, t-1}\right]
\end{aligned}
$$

[^9]where $u \sim N(0, \Sigma), \Sigma=\tau^{-1} I_{N}$. The $(N(T-1) \times N m)$ matrix $F$ of the $m$ common trends is a blockdiagonal matrix where each $(T-1 \times m)$ sub block $f$ is replicated $N$ times and $\Gamma$ is the $(N m \times 1)$ individual varying coefficients vector:
\[

F=I_{N} \otimes f with f=\left($$
\begin{array}{ccc}
f_{21} & \ldots & f_{2 m} \\
\ldots & \ldots & \ldots \\
f_{T 1} & \ldots & f_{T m}
\end{array}
$$\right) and \Gamma=\operatorname{vec}\left($$
\begin{array}{cccc}
\gamma_{11} & \gamma_{21} & \ldots & \gamma_{N 1} \\
\gamma_{12} & \gamma_{22} & \ldots & \gamma_{N 2} \\
\ldots & \ldots & \ldots & \ldots \\
\gamma_{1 m} & \gamma_{2 m} & \ldots & \gamma_{N m}
\end{array}
$$\right)
\]

This model is usually estimated using the common correlated effects pooled estimator (CCEP) (see Pesaran (2006) and Chudik and Pesaran (2015a,b)). It can also be estimated using the quasimaximum likelihood (QML) estimator. We compare our $2 S$ bootstrap estimator with the CCEP estimator. ${ }^{25}$ We chose samples in which the time span is large $T=30$ or $T=50$ with small $(N=50)$ or medium $(N=100)$ number of individuals (in the spirit of Chudik and Pesaran (2015a) who vary $N$ and $T$ between 40 and 200 in their simulations).

Table 2 shows that the results of the $2 S$ bootstrap estimator are close to those of the CCEP estimator. Moreover, the RMSEs of $2 S$ bootstrap and CCEP are close each other. Even if one increases the size of $N$ and/or $T$, all estimators yield essentially the same parameter estimates and associated RMSEs (See Table B. 6 in the supplementary material). The computation time is slightly longer with our estimator given the bootstrap procedure and the use of the inverse $\left(F^{\prime} F\right)^{-1}$ where $F$ could be a huge block-diagonal matrix. In fact, the $2 S$ bootstrap computation times are 1.2 to 1.6 times longer than those of CCEP. ${ }^{26}$

### 3.1.5. The dynamic homogeneous panel data world with common correlated effects

Again, this model is usually estimated using the common correlated effects pooled estimator (CCEP) (see Pesaran (2006); Chudik and Pesaran (2015a,b)) or with the principal components estimators using quasi-maximum likelihood (QML) estimator (see Bai (2009) or Song (2013)). Since the $m$ common correlated effects, $f_{t}$, are unknown, we need to rewrite the general dynamic model (8) as follows:

$$
\begin{aligned}
y= & Z \theta+W b+u=Z \theta+F \Gamma+u \\
& \quad \text { with } Z_{i t}^{\prime}=\left[y_{i t-1}, X_{i t}^{\prime}\right], \theta=\left[\rho, \beta^{\prime}\right]^{\prime} \text { and } X_{i t}^{\prime}=\left[x_{i, t}, x_{i, t-1}\right]
\end{aligned}
$$

where the $(N(T-1) \times N m)$ matrix $F$ of the $m$ unobserved factors is still a blockdiagonal matrix where each $((T-1) \times m)$ sub block $f$ is replicated $N$ times but $f$ should be approximated by known variables. Similar to the Hausman-Taylor case (see (24)), we can approximate the $((T-1) \times m) f$

[^10]matrix with a $\left((T-1) \times K_{1}\right) f^{*}$ matrix of the within time transformation ${ }^{27}$ of $Z_{i t}$ :
\[

$$
\begin{gathered}
f^{*}=\left(\begin{array}{c}
f_{2}^{*} \\
\cdots \\
f_{T}^{*}
\end{array}\right) \quad \text { where } f_{t}^{*}=\left[\left(\bar{y}_{-1, t}-\overline{\bar{y}}_{-1}\right),\left(\bar{x}_{t}-\overline{\bar{x}}\right),\left(\bar{x}_{-1, t}-\overline{\bar{x}}_{-1}\right)\right] \\
\text { with } \bar{x}_{t}=(1 / N) \sum_{i=1}^{N} x_{i t}, \overline{\bar{x}}=(1 / N T) \sum_{i=1}^{N} \sum_{t=2}^{T} x_{i t},
\end{gathered}
$$
\]

or as Chudik and Pesaran (2015a) by the time means of the dependent and explanatory variables: $f_{t}^{*}=\left[\bar{y}_{t}, \bar{y}_{-1, t}, \bar{x}_{t}, \bar{x}_{-1, t}\right] \cdot{ }^{28}$ We follow the method of Chudik and Pesaran (2015a,b) by introducing the time means of the dependent and explanatory variables instead of introducing only the within time transformation of the explanatory variables $Z_{i t}^{\prime}$. Then, the product $F \Gamma$ is approximated with the product $F^{*} \Gamma^{*}$ where the factor loadings $\Gamma^{*}$ is a $\left(N K_{1} \times 1\right)$ vector and $F^{*}$ is a $\left(N(T-1) \times N K_{1}\right)$ matrix of the time means of $Y$ and $Z$.

Table 2 shows that the results of the $2 S$ bootstrap are very close to those of the dynamic CCEP estimator. However, the RMSE is slightly smaller for CCEP than $2 S$ bootstrap. ${ }^{29}$ Once again, the computation time is longer with our estimator as the $2 S$ bootstrap computation times are 1.4 to 1.6 times longer than those of CCEP. ${ }^{30}$

### 3.1.6. The dynamic heterogeneous panel data world with common correlated effects

The dynamic heterogeneous panel data world with common factors is defined as:

$$
y_{i t}=\rho_{i} y_{i, t-1}+x_{i t} \beta_{1 i}+x_{i, t-1} \beta_{2 i}+f_{t}^{\prime} \gamma_{i}+u_{i t}=Z_{i t}^{\prime} \theta_{i}+f_{t}^{\prime} \gamma_{i}+u_{i t}
$$

where $Z_{i t}^{\prime}=\left[y_{i t-1}, X_{i t}^{\prime}\right], \theta_{i}^{\prime}=\left[\rho_{i}, \beta_{i}^{\prime}\right]^{\prime}$ and $X_{i t}^{\prime}=\left[x_{i, t}, x_{i, t-1}\right]$. This model is usually estimated using the common correlated effects mean group estimator (CCEMG) (see Pesaran (2006) and Chudik and Pesaran (2015a,b)). It could also be estimated using the quasi-maximum likelihood (QML) estimator. So we compare the mean coefficients $\widehat{\bar{\theta}}=(1 / N) \sum_{i=1}^{N} \widehat{\theta}_{i}$ of our 2S bootstrap estimator with the CCEMG estimator. ${ }^{31}$

While the bottom panel of Table 2 gives insights on the distribution of $\rho_{i}$ and $\beta_{1 i}$ for different sample sizes, the panel of Table 2 located just above gives the estimated values of the mean coefficients $\bar{\rho}, \bar{\beta}_{1}$, the estimated values of $\beta_{2}$ and $\sigma_{u}^{2}$, their standard deviations and their RMSE's. Table 2 shows that the results of the $2 S$ bootstrap estimator are close to those of the CCEMG estimator but the bias of $\sigma_{u}^{2}$ is slightly larger for CCEMG. The RMSEs results are mixed. 2S bootstrap gives smaller RMSE for $\rho$ and $\sigma_{u}^{2}$ than CCEMG, but CCEMG gives a smaller RMSE for $\bar{\beta}_{1}$. The results

[^11]for $\beta_{2}$ depend on the sample size. For $\bar{\beta}_{1}$ the bias is $2.5 \%$ for $N=100, T=30$, (resp. $5.7 \%$ for $N=50, T=50)^{32}$ for the $2 S$ bootstrap estimator as compared to those of the CCEMG estimator $(-1 \%$, resp. $(-0.8 \%))$. For the residuals' variance $\sigma_{u}^{2}$, the bias increases with the time dimension for both estimators but to a lesser extent for $2 S$ bootstrap. However, all the estimators yield roughly the same parameter estimates. Once again, the computation time is longer with our estimator as the $2 S$ bootstrap computation times are 1.3 to 1.6 times longer than those of CCEMG. ${ }^{33}$

## 4. Conclusion

To our knowledge, our paper is the first to analyze the dynamic linear panel data model using an $\varepsilon$-contamination approach within a two-stage hierarchical approach. The main benefit of this approach is its ability to extract more information from the data than the classical Bayes estimator with a single base prior. In addition, we show that our approach encompasses a variety of classical or frequentist specifications. We estimate the Type-II maximum likelihood (ML-II) posterior distribution of the slope coefficients and the individual effects using a two-step procedure. The posterior distribution is a convex combination of the conditional posterior densities derived from the elicited prior and the $\varepsilon$-contaminated prior. Thus if the base prior is consistent with the data, more weight is given to the conditional posterior density derived from the former. Otherwise, more weight is given to the latter.

The finite sample performance of the two-stage hierarchical models is investigated using extensive Monte Carlo experiments. The experimental design includes a random effects world, a Chamberlain-type fixed effects world, a Hausman-Taylor-type world and worlds with homogeneous/heterogeneous slopes and cross-sectional dependence. The simulation results underscore the relatively good performance of the two-stage hierarchy estimator, irrespective of the data generating process considered. The biases and the RMSEs are close and sometimes smaller than those of the conventional (classical) estimators. Although not reported for the sake of brevity, a thorough analysis of the sensitivity of our estimators to the contamination part of the prior distribution shows that parameter estimates are relatively stable. ${ }^{34}$ Likewise, the robustness of our estimators when the remainder disturbances are assumed to follow a right-skewed $t$-distribution is investigated and shown to behave well in terms of precision and bias relative to classical estimators. ${ }^{35}$

The robust Bayesian approach we propose is arguably a useful all-in-one panel data estimator. Because it embeds a variety of estimators, it can be used straightforwardly to estimate dynamic panel data models under many alternative stochastic specifications. Unlike classical estimators, there is no need to have a custom estimator for each possible DGP or to settle for those available in standard software suites.

We reckon that our estimator contributes only marginally to those already available in the literature. Our main contribution is to propose an estimator that allows the analysts to focus on the stochastic specification of their model. This is because our estimator is easily amenable to

[^12]many specifications in addition to those already presented in this paper. These include models with individual and time random effects in unknown common factors, spatial structures (autoregressive spatial, space-time), etc. We leave these for future work.

A. Uniform distribution, derivation of the mean and variance of the ML-II posterior density of $\rho$ and some Monte Carlo results
A.1. Uniform distribution and derivation of the mean and variance of the ML-II posterior density of $\rho$
Following Singh and Chaturvedi (2012) (see also Shrivastava et al. (2019)), and for deriving the posterior density of $\rho$, given $(\beta, b)$, we write:

$$
y^{\circ}=(y-X \beta-W b)=\rho y_{-1}+u
$$

the probability density function (pdf) of $y^{\circ}$, given the observables and the parameters, is:

$$
p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right)=\left(\frac{\tau}{2 \pi}\right)^{\frac{N(T-1)}{2}} \exp \left(-\frac{\tau}{2}\left(y^{\circ}-\rho y_{-1}\right)^{\prime}\left(y^{\circ}-\rho y_{-1}\right)\right)
$$

Let $\widehat{\rho}(\beta, b)=\left(y_{-1}^{\prime} y_{-1}\right)^{-1} y_{-1}^{\prime} y^{\circ}=\left(\Lambda_{y}\right)^{-1} y_{-1}^{\prime} y^{\circ}$, then following the derivation of (eq.16) in the technical appendix (pp 6-7) of Baltagi et al. (2018), we can write:

$$
\left(y^{\circ}-\rho y_{-1}\right)^{\prime}\left(y^{\circ}-\rho y_{-1}\right)=\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}
$$

with

$$
\varphi(\beta, b)=\left(y^{\circ}-\widehat{\rho}(\beta, b) y_{-1}\right)^{\prime}\left(y^{\circ}-\widehat{\rho}(\beta, b) y_{-1}\right)
$$

and

$$
\widehat{\rho}(\beta, b)=\left(y_{-1}^{\prime} y_{-1}\right)^{-1} y_{-1}^{\prime} y^{\circ}=\Lambda_{y}^{-1} y_{-1}^{\prime} y^{\circ}
$$

then

$$
p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right)=\left(\frac{\tau}{2 \pi}\right)^{\frac{N(T-1)}{2}} \exp \left(-\frac{\tau}{2}\left\{\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right\}\right)
$$

As the precision $\tau$ is assumed to have a vague prior $p(\tau) \propto \tau^{-1}$ and as $|\rho|<1$ is assumed to be $U(-1,1)$, the conditional posterior density of $\rho$, given $(\beta, b)$ is defined by:

$$
\begin{equation*}
\pi^{*}(\rho \mid \beta, b)=\frac{\int_{0}^{\infty} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \tau}{\int_{0}^{\infty} \int_{-1}^{1} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \rho d \tau} \tag{A.1}
\end{equation*}
$$

where

$$
p(\rho)=\frac{1}{2} \text { and } p(\tau)=\frac{1}{\tau}
$$

So, the numerator of $\pi^{*}(\rho \mid \beta, b)$ can be written as:

$$
\begin{aligned}
\int_{0}^{\infty} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \tau= & \int_{0}^{\infty}\left(\frac{1}{2}\right)\left(\frac{1}{\tau}\right)\left(\frac{\tau}{2 \pi}\right)^{\frac{N(T-1)}{2}} \\
& \times \exp \left(-\frac{\tau}{2}\left\{\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right\}\right) d \tau
\end{aligned}
$$

$$
\begin{aligned}
\int_{0}^{\infty} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \tau= & \left(\frac{1}{2}\right)\left(\frac{1}{2 \pi}\right)^{\frac{N(T-1)}{2}} \\
& \times \int_{0}^{\infty}\left[\begin{array}{c}
(\tau)^{\frac{N(T-1)}{2}-1} \\
\times \exp \left(-\frac{\tau}{2}\left\{\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right\}\right)
\end{array}\right] d \tau
\end{aligned}
$$

As $\int_{0}^{\infty} \tau^{x-1} \exp \left[-\frac{\tau}{2} r\right] d \tau=(2 / r)^{x} \Gamma(x)$, then

$$
\int_{0}^{\infty} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \tau=\frac{\Gamma\left(\frac{N(T-1)}{N}\right)}{2(\pi)^{\frac{N(T-1)}{2}}}\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}}
$$

The denominator of the conditional posterior density of $\rho$ is

$$
\int_{0}^{\infty} \int_{-1}^{1} p(\rho) p(\tau) p\left(y^{\circ} \mid y_{-1}, \rho, \tau\right) d \rho d \tau=\frac{\Gamma\left(\frac{N(T-1)}{2}\right)}{2(\pi)^{\frac{N(T-1)}{2}}} \int_{-1}^{1}\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}} d \rho
$$

then, the conditional posterior density of $\rho$, given $(\beta, b)$ is defined by:

$$
\begin{equation*}
\pi^{*}(\rho \mid \beta, b)=\frac{\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}}}{\int_{-1}^{1}\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}} d \rho} \tag{A.2}
\end{equation*}
$$

Let us derive the denominator of the previous expression

$$
\begin{aligned}
A & =\int_{-1}^{1}\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}} d \rho \\
& =[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \int_{-1}^{1}\left[1+\frac{\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}}{\varphi(\beta, b)}\right]^{-\frac{N(T-1)}{2}} d \rho \\
& =[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}} \int_{-\sqrt{\frac{\Lambda y}{\varphi(\beta, b)}}(1+\widehat{\rho}(\beta, b))}^{\sqrt{\frac{\Lambda y}{\varphi(\beta, b)}}(1-\widehat{\rho}(\beta, b))}\left(1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t
\end{aligned}
$$

$$
\begin{align*}
& A=[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}}\left[\int_{-\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}}(1+\widehat{\rho}(\beta, b))\right. \\
& 0 \\
&\left.=\left[1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t+\int_{0}^{\sqrt{\frac{\Lambda y}{\varphi(\beta, b)}}(1-\widehat{\rho}(\beta, b))}\left(1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t\right]  \tag{A.3}\\
&=[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}}\left[\int_{0}^{\sqrt{\frac{\Lambda y}{\varphi(\beta, b)}}(1+\widehat{\rho}(\beta, b))}\left(1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t+\right]_{0}^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}}\left[I_{1}+I_{2}\right]
\end{align*}
$$

Now taking the transformation $\eta=\frac{t^{2}}{1+t^{2}}$, then

$$
\left(1+t^{2}\right)=(1-\eta)^{-1} \text { and } d t=\frac{1}{2} \eta^{-\frac{1}{2}}(1-\eta)^{-3 / 2} d \eta
$$

and we obtain $I_{1}$ as ${ }^{1}$

$$
\begin{gather*}
I_{1}=\int_{0}^{\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1+\widehat{\rho}(\beta, b))}\left(1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t=\frac{1}{2} \int_{0}^{\zeta_{1}} \eta^{-\frac{1}{2}}(1-\eta)^{\frac{N(T-1)-3}{2}} d \eta  \tag{A.4}\\
\text { where } \zeta_{1}=\frac{\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}}{\left[1+\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}\right]} \\
I_{1}=\frac{1}{2} \zeta_{1}^{\frac{1}{2}} \int_{0}^{1} z^{-\frac{1}{2}}\left(1-\zeta_{1} z\right)^{\frac{N(T-1)-3}{2}} d z=\frac{1}{2} \zeta_{1}^{\frac{1}{2}} \frac{\Gamma(1 / 2)}{\Gamma(3 / 2)} \times{ }_{2} F_{1}\left(-\frac{N(T-1)-3}{2} ; \frac{1}{2} ; \frac{3}{2} ; \zeta_{1}\right) \\
=\zeta_{1}^{\frac{1}{2}} \times{ }_{2} F_{1}\left(-\frac{N(T-1)-3}{2} ; \frac{1}{2} ; \frac{3}{2} ; \zeta_{1}\right) \tag{A.5}
\end{gather*}
$$

Using the Pfaff's transformation:

$$
{ }_{2} F_{1}\left(a_{1} ; a_{2} ; a_{3} ; z\right)=(1-z)^{-a_{2}} \times{ }_{2} F_{1}\left(a_{3}-a_{1} ; a_{2} ; a_{3} ; \frac{z}{z-1}\right)
$$

[^14]where ${ }_{2} F_{1}\left(a_{1} ; a_{2} ; a_{3} ; z\right)$ is the Gaussian hypergeometric function.
we obtain
$$
{ }_{2} F_{1}\left(-\frac{N(T-1)-3}{2} ; \frac{1}{2} ; \frac{3}{2} ; \zeta_{1}\right)=\left(1-\zeta_{1}\right)^{-\frac{1}{2}} \times{ }_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ; \frac{\zeta_{1}}{\zeta_{1}-1}\right)
$$

Notice that

$$
\frac{\zeta_{1}}{\zeta_{1}-1}=-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2} \text { and } \frac{\zeta_{1}}{1-\zeta_{1}}=\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}
$$

Hence

$$
\begin{align*}
I_{1} & =\zeta_{1}^{\frac{1}{2}}\left(1-\zeta_{1}\right)^{-\frac{1}{2}} \times_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ; \frac{\zeta_{1}}{\zeta_{1}-1}\right) \\
& =\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1+\widehat{\rho}(\beta, b)) \times_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}\right) \tag{A.6}
\end{align*}
$$

Similarly we obtain

$$
\begin{gather*}
I_{2}=\int_{0}^{\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1-\widehat{\rho}(\beta, b))}\left(1+t^{2}\right)^{-\frac{N(T-1)}{2}} d t=\frac{1}{2} \int_{0}^{\zeta_{2}} \eta^{-\frac{1}{2}}(1-\eta)^{\frac{N(T-1)-3}{2}} d \eta  \tag{A.7}\\
\text { where } \zeta_{2}=\frac{\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}}{\left[1+\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}\right]} \\
I_{2}=\zeta_{2}^{\frac{1}{2}} \times_{2} F_{1}\left(-\frac{N(T-1)-3}{2} ; \frac{1}{2} ; \frac{3}{2} ; \zeta_{2}\right)=\zeta_{2}^{\frac{1}{2}}\left(1-\zeta_{2}\right)^{-\frac{1}{2}} \times_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ; \frac{\zeta_{2}}{\zeta_{2}-1}\right)
\end{gather*}
$$

Since

$$
\frac{\zeta_{2}}{\zeta_{2}-1}=-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2} \text { and } \frac{\zeta_{2}}{1-\zeta_{2}}=\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}
$$

Hence

$$
\begin{equation*}
I_{2}=\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1-\widehat{\rho}(\beta, b)) \times_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}\right) \tag{A.8}
\end{equation*}
$$

Then, the denominator of the conditional posterior density of $\rho$, given $(\beta, b)$, is

$$
\begin{aligned}
A & =[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}}\left[I_{1}+I_{2}\right] \\
& =[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}} \sqrt{\frac{\varphi(\beta, b)}{\Lambda_{y}}}\left[\begin{array}{c}
\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1+\widehat{\rho}(\beta, b)) \times{ }_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}\right) \\
+\sqrt{\frac{\Lambda_{y}}{\varphi(\beta, b)}}(1-\widehat{\rho}(\beta, b)) \times{ }_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}\right)
\end{array}\right]
\end{aligned}
$$

$$
A=[\varphi(\beta, b)]^{-\frac{N(T-1)}{2}}\left[\begin{array}{c}
(1+\widehat{\rho}(\beta, b)) \times{ }_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1+\widehat{\rho}(\beta, b))^{2}\right)  \tag{A.9}\\
+(1-\widehat{\rho}(\beta, b)) \times{ }_{2} F_{1}\left(\frac{N(T-1)}{2} ; \frac{1}{2} ; \frac{3}{2} ;-\frac{\Lambda_{y}}{\varphi(\beta, b)}(1-\widehat{\rho}(\beta, b))^{2}\right)
\end{array}\right]
$$

and the conditional posterior density of $\rho$, given $(\beta, b)$, is

$$
\begin{align*}
\pi^{*}(\rho \mid \beta, b) & =\frac{1}{A}\left[\varphi(\beta, b)+\Lambda_{y}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}} \\
& =\frac{\varphi(\beta, b)^{-\frac{N(T-1)}{2}}}{(A B)} B\left[1+\frac{\Sigma^{-1}}{N(T-1)-1}\{\rho-\widehat{\rho}(\beta, b)\}^{2}\right]^{-\frac{N(T-1)}{2}} \tag{A.10}
\end{align*}
$$

where ${ }^{2}$

$$
\begin{equation*}
\Sigma^{-1}=\frac{\Lambda_{y}[N(T-1)-1]}{\varphi(\beta, b)} \text { and } B=\frac{\Gamma\left(\frac{N(T-1)}{2}\right)}{\Gamma\left(\frac{N(T-1)}{2}-\frac{1}{2}\right)} \sqrt{\frac{\Lambda_{y}}{\pi \varphi(\beta, b)}} \tag{A.11}
\end{equation*}
$$

Since $N(T-1)$ is large, we can use the following result:

$$
\lim _{x \rightarrow \infty} x^{b-a} \frac{\Gamma(x+a)}{\Gamma(x+b)}=1 \rightarrow \lim _{x \rightarrow \infty} \frac{\Gamma(x+a)}{\Gamma(x+b)}=x^{a-b}
$$

with $x=N(T-1) / 2, a=0$ and $b=-1 / 2$ so that $B$ becomes: ${ }^{3}$

$$
\begin{equation*}
B=\sqrt{\frac{N(T-1)}{2 \pi} \frac{\Lambda_{y}}{\varphi(\beta, b)}} \tag{A.12}
\end{equation*}
$$

Then, the conditional posterior density of $\rho$, given $(\beta, b), \pi^{*}(\rho \mid \beta, b)$ is the pdf of a $t$-distribution $C^{-1} t_{\nu}(\widehat{\rho}(\beta, b), \Sigma)$ with shape matrix $\Sigma=\frac{\varphi(\beta, b)}{\Lambda_{y}[N(T-1)-1]}, \nu=N(T-1)-1$ degrees of freedom and

[^15]${ }^{3}$ The asymptotic expansion of the ratio of two Gamma functions is given by:
$$
\frac{\Gamma(x+a)}{\Gamma(x+b)} \sim x^{a-b} \sum_{k=0}^{\infty} \frac{G_{k}(a, b)}{x^{k}}
$$
where $G_{k}(a, b)=\binom{a-b}{k} B_{k}^{a-b+1}(a)$ and $B_{j}^{i}(n)$ is a generalized Bernoulli polynomial and $x=N(T-1) / 2, a=0$, $b=-1 / 2$. Using the computational knowledge engine Wolfram alpha (https://www.wolframalpha.com) with the command Series[Gamma[n/2]/Gamma[(n - 1)/2], \{n, [Infinity], 3\}], we get:
$\frac{\Gamma\left(\frac{N(T-1)}{2}\right)}{\Gamma\left(\frac{N(T-1)-1}{2}\right)} \sim \sqrt{\frac{N(T-1)}{2}}-\frac{3}{4 \sqrt{2 N(T-1)}}-\frac{7}{32 \sqrt{2(N(T-1))^{3}}}+\mathcal{O}\left(\frac{1}{(N(T-1))^{2}}\right)=\sqrt{\frac{N(T-1)}{2}}$ as $N(T-1) \rightarrow \infty$
$C=A \cdot B \cdot \varphi(\beta, b)^{\frac{N(T-1)}{2}}=\sqrt{\frac{N(T-1)}{2 \pi}}\left(I_{1}+I_{2}\right)$. Using the results of Kotz and Nadarajah $(2004)^{4}$, the mean of the posterior density of $\rho$ is:
\[

$$
\begin{equation*}
\widehat{\rho}=C^{-1} \widehat{\rho}(\beta, b) \tag{A.13}
\end{equation*}
$$

\]

and the variance of the posterior density of $\rho$ is

$$
\begin{equation*}
\operatorname{Var}[\widehat{\rho}]=C^{-2} \cdot \frac{\nu}{\nu-2} \Sigma \tag{A.14}
\end{equation*}
$$

If $\rho$ is assumed to be $U(-1,1)$, then we get a three-step approach. For the dynamic specification: $y=\rho y_{-1}+X \beta+W b+u$, we can integrate first with respect to $(\beta, \tau)$ given $b$ and $\rho$, and then, conditional on $\beta$ and $\rho$, we can next integrate with respect to $(b, \tau)$ and last, we can integrate with respect to $\rho$ given $(\beta, b)$.

1. Let $y^{*}=\left(y-\rho y_{-1}-W b\right)$. Derive the conditional ML-II posterior distribution of $\beta$ given the specific effects $b$ and $\rho$ as in the section 2.3 .1 of the main text.
2. Let $\widetilde{y}=\left(y-\rho y_{-1}-X \beta\right)$. Derive the conditional ML-II posterior distribution of $b$ given the coefficients $\beta$ and $\rho$ as in the section 2.3.2 of the main text.
3. Let $y^{\circ}=(y-X \beta-W b)$. Derive the conditional ML-II posterior distribution of $\rho$ given the coefficients $\beta$ and $b$ as in the previous section A.1.
As the mean and variance of $\rho$ are exactly defined, we do not need to introduce an $\varepsilon$-contamination class of prior distributions for $\rho$ at the second stage of the hierarchy. This was initially our first goal. Unfortunately, the results obtained on a Monte Carlo simulation study (see section A.2) provide biased estimates of $\rho, \beta$ and residual variances. That is why we assume a Zellner $g$-prior, for the $\theta\left(=\left[\rho, \beta^{\prime}\right]^{\prime}\right)$ vector encompassing the coefficient of the lagged dependent variable $y_{i, t-1}$ and those of the explanatory variables $X_{i t}^{\prime}$. Thus, we do not impose stationarity constraints like many authors and we respect the philosophy of $\varepsilon$-contamination class using data-driven priors.

## A.2. Some Monte Carlo results

We run a Monte Carlo simulation study for the dynamic random effects world comparing different robust Bayesian estimators. As previously in the main text, we run the two-stage approach with individual block resampling bootstrap assuming a Zellner $g$-prior, for the $\theta\left(=\left[\rho, \beta^{\prime}\right]^{\prime}\right)$ vector encompassing the coefficient of the lagged dependent variable $y_{i, t-1}$ and those of the explanatory variables $X_{i t}^{\prime}$. We introduce a two-stage three step approach when $\rho \sim U(-1,1)$. When the initial value of $\rho$ is drawn for a uniform distribution $U(-1,1)$, results are strongly biased as shown on Table A.1. Even if we initialize $\rho$ with its OLS estimator on the pooled model, the results, if they improve, are still slightly biased and the computation time is much longer than that of the two-stage two-step approach. The last panel of Table A. 1 shows that less biased results are obtained with initial value of $\rho$ coming from a LSDV estimator of $\rho$ (rather than an OLS estimator of $\rho$ ). ${ }^{5}$ So, there is a significant cost to pay when using a constrained $\rho$ coefficient because it is not enough to

[^16]generate it initially from a $U(-1,1)$ but it must first be estimated from an LSDV estimator which also greatly increases the computation time and that the bias on $\sigma_{\mu}^{2}$ increases. All this confirms our idea that we are doing well not to impose stationarity constraints like many authors and respect in this sense the philosophy of $\varepsilon$-contamination class using data-driven priors.

Table A.1: Dynamic Random Effects World
$N=100, T=10, \varepsilon=0.5$, Replications $=1,000$

(*) When $T=30$, we restrict the exercise to only 500 replications, not because of our estimator under $R$ but because of the size of the simulated database and its reading under Stata. Indeed, for 1,000 replications and $T=30$, one must read, under Stata, $(1+4+30) \times 1,000=35,000$ variables of size $(N T, 1)$ ! Even with a 64 -bit computer and Stata (MP and S), only 32,767 variables can be read. On the other hand, with our code under $R$, there is no limitation of that order.

## C. A simple and efficient way to drastically reduce the computation time of our Bayesian two-stage estimator.

The first stage of the Gaussian dynamic linear mixed model (eq.(10) in the main text) is given by

$$
\begin{equation*}
y=Z \theta+W b+u, u \sim N\left(0, \tau^{-1} I_{N T}\right) \tag{C.15}
\end{equation*}
$$

where $y$ is $(N(T-1) \times 1)$. $Z$ is $\left(N(T-1) \times\left(K_{x}+1\right)\right), W$ is $\left(N(T-1) \times K_{2}\right)$ with $K_{2}=N k_{2}$ and $u$ is $(N(T-1) \times 1)$. The mean of the ML-II posterior density of $\theta$ is:

$$
\begin{align*}
\widehat{\theta}_{M L-I I} & =E\left[\widehat{\pi}^{*}\left(\theta \mid g_{0}\right)\right]=\widehat{\lambda}_{\theta, g_{0}} E\left[\pi_{0}^{*}\left(\theta \mid g_{0}\right)\right]+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) E\left[\widehat{q}^{*}\left(\theta \mid g_{0}\right)\right]  \tag{C.16}\\
& =\widehat{\lambda}_{\theta, g_{0}} \theta_{*}\left(b \mid g_{0}\right)+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \widehat{\theta}_{E B}\left(b \mid g_{0}\right)
\end{align*}
$$

Baltagi et al. (2018) have shown that the ML-II posterior variance-covariance matrix of $\theta$ is given by

$$
\begin{align*}
\operatorname{Var}\left(\widehat{\theta}_{M L-I I}\right) & =\widehat{\lambda}_{\theta, g_{0}} \operatorname{Var}\left[\pi_{0}^{*}\left(\theta \mid g_{0}\right)\right]+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \operatorname{Var}\left[\widehat{q}^{*}\left(\theta \mid g_{0}\right)\right]  \tag{C.17}\\
& +\widehat{\lambda}_{\theta, g_{0}}\left(1-\widehat{\lambda}_{\theta, g_{0}}\right)\left(\theta_{*}\left(b \mid g_{0}\right)-\widehat{\theta}_{E B}\left(b \mid g_{0}\right)\right)\left(\theta_{*}\left(b \mid g_{0}\right)-\widehat{\theta}_{E B}\left(b \mid g_{0}\right)\right)^{\prime}
\end{align*}
$$

Many have raised concerns about the unbiasedness of the posterior variance-covariance matrix of $\widehat{\theta}_{M L-I I}$. Indeed, it will be biased towards zero as $\widehat{\lambda}_{\theta, g_{0}} \rightarrow 0$ and converge to the empirical variance which is known to underestimate the true variance (see e.g. Berger and Berliner (1986); Gilks et al. (1997); Robert (2007)). To solve this problem, Baltagi et al. (2018) have proposed two different strategies to approximate it, each with different desirable properties: MCMC with multivariate $t$-distributions or individual block resampling bootstrap. They have shown that fortunately, one needs as few as 20 bootstrap samples to achieve acceptable results. They also showed that the bootstrap method had some advantages over the MCMC method, especially in terms of computation time.

Computation times can be improved by using the Choleski decomposition for matrices inversion ${ }^{6}$ for all the tested worlds (RE, Chamberlain, Hausman-Taylor, CCE). Additionally, multivariate normal random vectors in the common correlated effects (CCE) models could make use of the sparse matrices. ${ }^{7}$ Yet, the efficiency gains would be relatively modest given the number of bootstrap draws that need to be generated.

An alternative approach arises if we exploit the intrinsic features of the distributions of the Bayes estimate $\theta_{*}\left(b \mid g_{0}\right)$ for the prior distribution $\pi_{0}(\theta, \tau)$ and the empirical Bayes estimate $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$ for the contaminated prior distribution $q(\theta, \tau)$.
We have shown that $\pi_{0}^{*}\left(\theta \mid g_{0}\right)$ is the pdf of a multivariate $t$-distribution $t_{K_{1}}\left(\theta_{*}\left(b \mid g_{0}\right), \Sigma_{\theta_{*}\left(b \mid g_{0}\right)}, N(T-1)\right)$

[^18]and $\widehat{q}^{*}(\theta)$ is the pdf of a multivariate $t$-distribution $t_{K_{1}}\left(\widehat{\theta}_{E B}\left(b \mid g_{0}\right), \Sigma_{\widehat{\theta}_{E B}\left(b \mid g_{0}\right)}, N(T-1)\right)$ where the mean vectors $\theta_{*}\left(b \mid g_{0}\right)$ and $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$ are given by
$$
\theta_{*}\left(b \mid g_{0}\right)=\frac{\widehat{\theta}(b)+g_{0} \theta_{0} \iota_{K_{1}}}{g_{0}+1}, \widehat{\theta}_{E B}\left(b \mid g_{0}\right)=\frac{\widehat{\theta}(b)+\widehat{g}_{q} \widehat{\theta}_{q} \iota_{K_{1}}}{\widehat{g}_{q}+1} .
$$
and the variance-covariance matrices $\Sigma_{\theta_{*}\left(b \mid g_{0}\right)}$ and $\Sigma_{\widehat{\theta}_{E B}\left(b \mid g_{0}\right)}$ are given by
\[

$$
\begin{aligned}
\Sigma_{\theta_{*}\left(b \mid g_{0}\right)} & =\left(\frac{\xi_{0, \theta} M_{0, \theta}^{-1}}{N(T-1)-2}\right) \text { with } M_{0, \theta}=\frac{\left(g_{0}+1\right)}{v(b)} \Lambda_{Z} \text { and } \xi_{0, \theta}=1+\left(\frac{g_{0}}{g_{0}+1}\right)\left(\frac{R_{\theta_{0}}^{2}}{1-R_{\theta_{0}}^{2}}\right) . \\
\Sigma_{\widehat{\theta}_{E B}\left(b \mid g_{0}\right)} & =\left(\frac{\xi_{q, \theta} M_{q, \theta}^{-1}}{N(T-1)-2}\right) \text { with } M_{q, \theta}=\left(\frac{\left(\widehat{g}_{q}+1\right)}{v(b)}\right) \Lambda_{Z} \text { and } \xi_{q, \theta}=1+\left(\frac{\widehat{g}_{q}}{\widehat{g}_{q}+1}\right)\left(\frac{R_{\widehat{\theta}_{q}}^{2}}{1-R_{\widehat{\theta}_{q}}^{2}}\right) .
\end{aligned}
$$
\]

Thus the ML-II posterior density of $\theta$ in (C.16) is a two-component finite mixture of multivariate $t$-distributions. Its pdf is given by

$$
\begin{equation*}
\pi\left(\tilde{\theta}_{M L-I I}\right)=\sum_{h=1}^{2} \varrho_{h} \pi_{h}\left(\widehat{\theta}_{M L-I I}, m_{h}, \Sigma_{h}, \nu_{h}\right) \tag{C.18}
\end{equation*}
$$

where $\pi_{h}\left(\widehat{\theta}_{M L-I I}, m_{h}, \Sigma_{h}, \nu_{h}\right)$ denotes the $h$-th pdf of the mixture model with location parameter $m_{h}$, scale matrix $\Sigma_{h}$ and degrees of freedom $\nu_{h}$. The mixing proportions satisfy $\varrho_{h} \geq 0(h=1,2)$ and $\sum_{h=1}^{2} \varrho_{h}=1$. In our case, $\nu_{h}=N(T-1), \forall h, m_{1}=\theta_{*}\left(b \mid g_{0}\right), m_{2}=\hat{\theta}_{E B}\left(b \mid g_{0}\right), \Sigma_{1}=\Sigma_{\theta_{*}\left(b \mid g_{0}\right)}$, $\Sigma_{2}=\Sigma_{\widehat{\theta}_{E B}\left(b \mid g_{0}\right)}, \varrho_{1}=\widehat{\lambda}_{\theta, g_{0}}$ and $\varrho_{2}=1-\widehat{\lambda}_{\theta, g_{0}}$.

Derivations of the location parameter and the scale matrix of a mixture of multivariate $t$ distributions is a very difficult task (see for instance Walker and Saw (1978), Peel and McLachlan (2000), Kotz and Nadarajah (2004), McLachlan and Peel (2004), Mengersen et al. (2011) among others). Parameter estimates of the mixture of $t$-distributions is generally obtained via an EM algorithm. McLachlan and Lee (2013) have proposed a EMMIXuskew R package for generating and fitting mixture of multivariate skewed (and non-skewed) $t$ distributions via the EM Algorithm. Based on the command rfmmst of this package, and given the parameters of the two components defined above, one can generate 1000 (or more) random samples of $K_{1}$-dimensional multivariate $t$ observations with location parameter $m_{h}$, scale matrix $\Sigma_{h}$ and degrees of freedom $\nu_{h}$ for $h=1,2$, and hence sample from the mixture of these two components to generate as many random vectors of $\tilde{\theta}_{M L-I I}$. The variances of the $K_{1}$ parameters can then be computed over these 1000 (or more) random samples.

After extensive experimentation, it was found that the estimated variances were slightly underestimated compared to those obtained with the bootstrap method. We therefore propose to correct the variances with the following multiplicative factor: $\sqrt{k_{2}}(1+\sqrt{\hat{r}})^{2}$. In the RE, Chamberlain and Hausman-Taylor worlds, $\hat{r}=\hat{\sigma}_{\mu}^{2} /\left(\hat{\sigma}_{\mu}^{2}+\hat{\sigma}_{u}^{2}\right)$ is the fraction of the variance $\left(\hat{\sigma}_{\mu}^{2}+\hat{\sigma}_{u}^{2}\right)$ due to the
specific effects $\mu_{i}$, with $\hat{\sigma}_{u}^{2}=\hat{\tau}^{-1}$ and $k_{2}$ is the number of covariates in W in eq.(C.15). ${ }^{8}$ In the common correlated effects worlds (CCE) worlds, ${ }^{9} \hat{\sigma}_{\mu}^{2}=\operatorname{Var}[\Gamma]$.

For the random effects world, and when the true $r=0.8$ (see Table C.1) ${ }^{10}$, the difference between the estimated standard errors of the parameters $\rho$ and $\beta$ from the bootstrap and mixture approaches is at most 0.007 , and decreases when $N$ and $T$ increase. The more $r$ decreases, the more the difference between the estimated standard errors (bootstrap versus mixture) decreases until reaching as little as $10^{-3}$ (see Tables C. 2 and C.3). We also note that whatever the sample sizes $N, T$ or the value of $r$, the bias of the GMM estimator of $\hat{\sigma}_{\mu}^{2}$, and to a lesser extent that of $\hat{\sigma}_{u}^{2}$, is bigger than those of our Bayesian two-stage estimator $(B 2 S)$ and the QMLE estimator.

In the Chamberlain-type fixed effects worlds, the differences between the standard errors from the bootstrap and the mixture approaches are slightly larger than those of the random effects (see Table C.4). Note that the standard errors of $\beta_{11}$ and $\beta_{12}$ - from the mixture of $t$-distributions - are approximately $30 \%$ larger than those computed by the bootstrap approach. Yet the more important difference concerns the standard error of $\beta_{2}$, which is twice as large. However, as these standard errors are small, the $95 \%$ confidence intervals are nevertheless very similar (for instance, for $\beta_{2}$ : $[0.95 ; 1.04]$ for se_boot and $[0.90 ; 1.08]$ for se_mixt for $N=100$ and $\left.T=10\right)$. Increasing $N$ and $T$ greatly reduces the differences between the two approaches. Thus, for $N=200$ and $T=30$, the $95 \%$ confidence intervals of $\beta_{2}$ are $[0.98 ; 1.01]$ for se_boot and $[0.96 ; 1.03]$ for se_mixt and the differences are marginal.

For the Hausman-Taylor world, the mixture approach leads to similar standard errors for $\rho$, $\beta_{11}$ and $\beta_{12}$ but generates a small bias for $\beta_{2}$, and yet more important downward biases for the standard errors of the parameters of the time-invariant variables $\eta_{1}$ (the constant) and to a lesser extent for $\eta_{2}$ (see Table C.5). As $N$ increases and especially when $T$ increases, these biases reduce but that of the constant $\eta_{1}$ always remains bigger.

For the common correlated effects world with common trends, we find few differences between standard errors arising from the bootstrap and the mixture approaches and these differences taper off as $N$ increases (see Table C.6). We find the same type of results for the common correlated effects world with unobserved common factors (see Table C.7).

In the case of the dynamic heterogeneous panel data world with common correlated unobserved effects, the correction factor needs to be modified slightly to take into account the average over all

[^19]individuals. The corrected variance of $\tilde{\theta}_{M L-I I}$ is computed as: ${ }^{11}$
\[

$$
\begin{aligned}
\operatorname{Var}\left[\tilde{\theta}_{M L-I I}\right]= & \frac{1}{N} \sum_{i=1}^{N} \operatorname{Var}\left[\tilde{\theta}_{i, M L-I I}\right]_{c o r} \\
& \text { with } \operatorname{Var}\left[\tilde{\theta}_{i, M L-I I}\right]_{c o r}=\operatorname{Var}\left[\tilde{\theta}_{i, M L-I I}\right] \sqrt{m N}\left(1+\sqrt{\hat{r}_{i}}\right)^{2} \\
& \text { and } \hat{r}_{i}=\operatorname{Var}\left[\hat{\gamma}_{i}\right] /\left(\operatorname{Var}\left[\hat{\gamma}_{i}\right]+\operatorname{Var}\left[\hat{u}_{i}\right]\right) .
\end{aligned}
$$
\]

This additional correction factor, $\sqrt{N}$, is somewhat reminescent of the results from Theorem 3 of Chudik and Pesaran (2015), which shows that the convergence rate of the CCEMG estimator $\hat{\theta}_{C C E M G}$ of $\theta$ is $\sqrt{N}$ due to the heterogeneity of the coefficients. Moreover, Chudik and Pesaran (2015) show that the ratio $N / T \rightarrow \kappa_{1}$, for some constant $0<\kappa_{1}<\infty$, is required for the derivation of the asymptotic distribution of $\hat{\theta}_{C C E M G}$ due to the time series bias and that it is unsuitable for panels with $T$ being small relative to $N .{ }^{12}$ Standard errors computed using the mixture approach are close to those from the bootstrap one except for the standard error of the coefficient $\rho$ of the lagged dependent variable which appears to be slightly downward biased (see Table C.8). When the sample size increases ( $N=200, T=30$ and $T=50$ ) (see Table C.9), the previous results are confirmed but the gain in computation time for the mixture approach is reduced from a factor of 10 to a factor of 6 , which is still considerable in a dynamic heterogeneous panel data world with common correlated effects.

As confirmed in Tables C. 1 to C.9, the standard errors calculated with the bootstrap method and those calculated with the mixture of $t$ distributions diverge slightly in some cases. Assuredly, the most impressive result concerns the gain in computation speed irrespective of the tested worlds. Yet, the small differences in the standard errors is a small price to pay to obtain $\varepsilon$-contamination estimators in a timely fashion. The computation time of the two-stage method using the mixture model to estimate the parameter variances is 10 times faster than the one using the bootstrap method. This also applies to approaches (GMM, QMLE, 2SQMLE, CCEP or CCEMG). With a larger sample size ( $N=200$ and $T=50$ ), a final confirmation is provided in Table C. 10 for the random effects world. ${ }^{13}$ The differences between the estimates for the Bayesian two-stage (B2S) estimator with se_boot, or with se_mixt, and those obtained with QMLE are marginal when the sample size is significantly increased. The difference in computation times is impressive (464 seconds for se_mixt, 3911 seconds for se_boot and 6150 seconds for QMLE for 1,000 replications). The advantage of our Bayesian two-stage estimator is pretty obvious. And because it has little computing time, it should be valuable for applied econometricians.

B2S : Bayesian two-stage estimation.
se_boot: standard errors computed with individual block resampling bootstrap.
se_mixt: standard errors of $\theta=\left(\rho, \beta^{\prime}\right)^{\prime}$ computed with mixture of $t$-distributions of $\theta_{*}\left(b \mid g_{0}\right)$ and $\widehat{\theta}_{E B}\left(b \mid g_{0}\right)$.
GMM: Arellano-Bond GMM estimation.
QMLE: quasi-maximum likelihood estimation.

B2S : Bayesian two-stage estimation. The parameters $\pi_{t}$ are omitted from the table.
se_boot: standard errors computed with individual block resampling bootstrap.
se_mixt: standard errors computed with mixture of $t$-distributions.
QMLE: quasi-maximum likelihood estimation. The parameters $\pi_{t}$ are omitted from the table.
(*) When $T=30$, we restrict the exercise to only 500 replications, not because of our estimator under $R$ but because of the size of the simulated database and its reading under Stata. Indeed, for 1,000 replications and $T=30$, one must read, under Stata, $(1+4+30) \times 1,000=35,000$ variables of size $(N T, 1)$ ! Even with a 64 -bit computer and Stata (MP and S), only 32,767 variables can be read. On the other hand, with our code under $R$, there is no limitation of that order.

## D. Sensitivity to $\varepsilon$-contamination values

Tables D. 1 and D. 2 investigate the sensitivity of the $2 S$ bootstrap estimator for the random effects world and for the heterogeneous panel data world with common correlated effects ${ }^{14}$ with respect to $\varepsilon$, the contamination part of the prior distributions, which varies between 0 and $90 \%$. As shown in Table D. 1 for the random effects world when $N=100$ and $T=10$, all the parameter estimates are insensitive to $\varepsilon$. The only noteworthy change concerns the estimated value of $\lambda_{\mu}\left(\equiv \lambda_{b, h_{0}}\right)$. It more or less corresponds to $(1-\varepsilon)$. This particular relation may occur whenever $\widehat{h} /(\widehat{h}+1)=$ $h_{0} /\left(h_{0}+1\right)$ and $R_{b_{0}}^{2} /\left(1-R_{b_{0}}^{2}\right)=R_{\widehat{b}_{q}}^{2} /\left(1-R_{\widehat{b}_{q}}^{2}\right)$ (see the definition of $\widehat{\lambda}_{b, h_{0}}$ in section 2.3.2 in the main text). The observed stability of the coefficients estimates stems from the fact that the base prior is not consistent with the data as the weight $\hat{\lambda}_{\theta} \rightarrow 0$. The ML-II posterior mean of $\theta$ is thus close to the posterior $\widehat{q}^{*}\left(\theta \mid g_{0}\right)$ and to the empirical Bayes estimator $\widehat{\theta}_{E B}\left(\mu \mid g_{0}\right)$. Hence, the numerical value of the $\varepsilon$-contamination, for $\varepsilon \neq 0$, does not seem to play an important role in our simulated worlds. Table D. 1 also reports the results when $\varepsilon$ is very close to zero $\left(\varepsilon=10^{-17}\right)$ and we get similar results. Lastly, we have also checked the extreme case when $\varepsilon=0$. The restricted ML-II estimator $(\varepsilon=0)$ constrains the model to rely exclusively on a base elicited prior which is implicitly assumed error-free. This is a strong assumption. This time, results are not strictly similar to those of $\varepsilon \neq 0$ but they are close to the true values except for $\sigma_{\mu}^{2}$ which has a fairly large upward bias $(11.4 \%)$ as well as a large RMSE. ${ }^{15}$

Table D. 2 shows similar results. All the parameter estimates are insensitive to $\varepsilon(\varepsilon \neq 0)$ for the heterogeneous panel data world with common correlated effects when $N=100$ and $T=30$. The only changes concern the estimated values of $\lambda_{\theta, g_{0}}$ and $\lambda_{\mu}\left(\equiv \lambda_{b, h_{0}}\right)$. While $\widehat{\lambda}_{\mu}\left(\equiv \widehat{\lambda}_{b, h_{0}}\right)$ changes inversely to $\varepsilon, \widehat{\lambda}_{\theta, g_{0}}$ has the shape of an inverted $J$ as $\varepsilon$ increases. As for the random effects world, when $\varepsilon=0$, the results are not strictly similar to those of $\varepsilon \neq 0$ but they are close to the true values except for $\sigma_{u}^{2}$ which has also a fairly large upward bias (23.8\%) as well as large standard error and RMSE. Whatever the world tested, results are insensitive to the exact value of $\varepsilon \neq 0$. This stems from the fact that the $2 S$ bootstrap estimator is data driven and implicitly adjusts the weights to the different values of $\varepsilon$-contamination. This may be why, even though the choice of $\varepsilon=0.5$ is somewhat arbitrary, the adjustment compensates for it not being optimal (see Berger (1985)).

## E. Departure from normality

Tables E. 1 and E. 2 investigate the robustness of the estimators to a non-normal framework for the random effects world and for the heterogeneous panel data world with common correlated effects. The remainder disturbances, $u_{i t}$, are now assumed to follow a right-skewed $t$-distribution with mean $=0$, degrees of freedom $\nu=3$, and skewing parameter $\gamma=2$ (see Fernández and Steel (1998), Baltagi et al. (2018)). ${ }^{16}$ Our $2 S$ bootstrap estimator behaves pretty much like the GMM and the QMLE for the random effects world when $N=100$ and $T=10$ (see Table E.1). Compared to the GMM estimator, our $2 S$ bootstrap estimator provides better estimates of $\sigma_{u}^{2}$ and $\sigma_{\mu}^{2}$ but it is the QML estimator that gives the estimates closest to the true values. Another interesting result concerns the standard errors and RMSEs of all the estimators. The presence of a right-skewed $t$-distribution greatly increases these values especially for $\sigma_{u}^{2}$.

Table E. 2 investigates the robustness of the CCEMG and $2 S$ bootstrap estimators to the rightskewed $t$-distribution for the heterogeneous panel data world with common correlated effects when $N=100$ and $T=30$. There are slight downward biases for the $\bar{\rho}$ mean coefficient, with that of CCEMG being larger than that of $2 S$ bootstrap ( $-16 \% v s-7.6 \%$ ) as well as slight upward bias for $\sigma_{u}^{2}$, that of CCEMG being larger than that of $2 S$ bootstrap $(5.6 \%$ vs $0.5 \%)$. However, for the $\bar{\beta}_{1}$ mean coefficient, it is the $2 S$ bootstrap estimator which has larger bias ( $17.2 \%$ vs $7.5 \%$ ). Finally, it can be noted that the RMSE of $\sigma_{u}^{2}$ is larger for the CCEMG estimator than for the $2 S$ bootstrap estimator.

[^22]where $f($.$) is the density of the t$ distribution with $\nu$ degrees of freedom.

## Robust dynamic panel data models using epsiloncontamination

Badi H. Baltagi, Department of Economics and Center for Policy Research, Syracuse University, Syracuse, New York, U.S.A.
Georges Bresson, Département de science économique, Université Pair-II, France Anoop Chaturvedi, Department of Statistics, University of Allahabad, India Guy Lacroix, Département d'économique, Université Laval

This paper is written in honor of M . Hashem Pesaran for his many contributions to econometrics. In particular, heterogeneous panel data, Bayesian estimation of dynamic panel data models, random coefficient models for panel data and cross-section dependence in panels.

We would like to thank Jean-Michel Etienne for help and support with Stata Mata codes. We also thank an anonymous referee and Cheng Hsiao for useful comments and suggestions. Many thanks to the participants of the 2020 Econometric Society/Bocconi University Virtual World Congress for fruitful comments. Anoop Chaturvedi gratefully acknowledges the Department of Economics, Université Paris II for his visiting professorship and facilities to carry out this work. The usual disclaimers apply disclaimers apply

[^0]:    ${ }^{1}$ For the dynamic fixed-effects model, see for instance Hsiao et al. (2002).
    ${ }^{2}$ In a Gaussian dynamic linear mixed model: $y_{i t}=\rho y_{i t-1}+X_{i t}^{\prime} \beta+W_{i t}^{\prime} b_{i}+u_{i t}, i=1, \ldots, N, t=2, \ldots, T$, as in our case (see (8) in section (2)), maximum likelihood analysis is subject to an initial condition problem if the permanent subject effects $b_{i}$ and the initial observations are correlated. In case of such correlation, possible options are a joint random prior (e.g., bivariate normal) involving $b_{i}$ and the first disturbance $u_{i 1}$ (Dorsett (1999)), or a prior for $b_{i}$ that is conditional on $y_{i 1}$, such as $b_{i} \mid y_{i 1} \sim N\left(\varphi y_{i 1}, \sigma_{1}^{2}\right)$ (see Hirano (2002) and Wooldridge (2005)).

[^1]:    ${ }^{3}$ Here we assume the homoskedasticity of $u_{i t}$. As the GMM or QML estimators are robust to the presence of time-series heteroskedasticity, one could introduce time-series heteroskedasticity as an ARCH processes or HAR-type models. We thank an anonymous referee for this suggestion. However, in that case, the derivation of the marginal likelihoods (or predictive densities) (see section 2.3) is quite involved. An extension along these lines is beyond the scope of the current paper and is more appropriately dealt with in a separate one.
    ${ }^{4}$ We thank an anonymous referee for this suggestion.

[^2]:    ${ }^{5}$ One could also use a one-step estimation of the ML-II posterior distribution. But in the one-step approach, the pdf of $y$ and the pdf of the base prior $\pi_{0}\left(\beta, b, \tau \mid g_{0}, h_{0}\right)$ need to be combined to get the predictive density. It thus leads to a complex expression whose integration with respect to $(\beta, b, \tau)$ may be involved.

[^3]:    ${ }^{6}$ Derivation can be found in the supplementary appendix of Baltagi et al. (2018).

[^4]:    ${ }^{7}$ Following Berger (1985), Baltagi et al. (2018) derived the analytical ML-II posterior variance-covariance matrix of $\theta$ (see the supplementary appendix of Baltagi et al. (2018)).
    ${ }^{8} \widehat{\lambda}_{b, h_{0}}$ is defined by the following elements $\widehat{h}, R_{b_{0}}, R_{\widehat{b}_{q}}, \widehat{b}(\theta), \widehat{b}_{q}$ which are analogous respectively to $\widehat{g}_{q}, R_{\theta_{0}}$, $R_{\widehat{\theta}_{q}}, \widehat{\theta}(b), \widehat{\theta}_{q}$ and where $W, \Lambda_{W}, \widetilde{y}, h_{0}, K_{2}, b_{0}, \iota_{K_{2}}$ replace $Z, \Lambda_{Z}, y^{*}, g_{0}, K_{1}, \theta_{0}, \iota_{K_{1}}$ of the preceeding subsection.

[^5]:    ${ }^{9}$ See the supplementary appendix of Baltagi et al. (2018).
    ${ }^{10}$ Increasing the number of bootstrap samples does not change the results but increases the computation time considerably.

[^6]:    ${ }^{11} \varepsilon=0.5$ is an arbitrary value. This implicitly assumes that the amount of error in the base elicited prior is $50 \%$. In other words, $\varepsilon=0.5$ means that we elicit the $\pi_{0}$ prior but feel we could be as much as $50 \%$ off (in terms of implied probability sets).
    ${ }^{12}$ We chose: $\theta_{0}=0, b_{0}=0$ and $\tau=1$.
    ${ }^{13}$ We use our own R codes for our Bayesian estimator, the $R$ package plm for the Arellano-Bond GMM estimator and the xtdpdqml Stata package for the QMLE. We use the same DGP set under R and Stata environments to compare the three methods. We thank Jean-Michel Etienne for his help and support with the full-blown programming language Mata of Stata.
    ${ }^{14}$ Recall that we use only $B R=20$ individual block bootstrap samples. Fortunately, the results are very robust to the value of $B R$. For instance, increasing $B R$ from 20 to 200 in the random effects world increases the computation time tenfold but yields practically the same results.

[^7]:    ${ }^{15}$ Whenever we discuss samples other than $(N=100, T=10)$ for the random effects, the Chamberlain-type fixed effects and the Hausman-Taylor worlds or $(N=100, T=30)$ for the commom correlated effects world, we refer the reader to Tables in section B in the supplementary material.
    ${ }^{16}$ The simulations were conducted using R version 3.3 .2 on a MacBook Pro, 2.8 GHz core i7 with 16 Go 1600 MGz DDR3 ram.
    ${ }^{17}$ Strictly speaking, we should mention "posterior means" and "posterior standard errors" whenever we refer to Bayesian estimates and "coefficients" and "standard errors" when discussing frequentist ones. For the sake of brevity, we will use "coefficients" and "standard errors" in both cases.
    ${ }^{18}$ See the supplementary material for more details.

[^8]:    ${ }^{19}$ When $\rho$ is close to the non-stationarity bounds (i.e., close to one), the QMLE, two-stage QMLE, CCEP and CCEMG estimators give unrealistic values of the variances $\sigma_{u}^{2}$ and $\sigma_{\mu}^{2}$ or cannot be computed.
    ${ }^{20}$ If they underline that it does not matter whether the initial values are treated as fixed constants or random variables when $N$ is fixed and $T$ is large, they point out that the treatment of initial values becomes important when $N$ is large. When one treats initial values as fixed constants, the QMLE is inconsistent if $T$ is fixed and $N \rightarrow \infty$. It becomes consistent but asymptotically biased of order $\sqrt{N / T^{3}}$ when both $N$ and $T$ are large. However, if the specific effects are correlated with the exogenous variables, the naive GLS estimator on fixed initial conditions is asymptotically biased of order $\sqrt{N / T}$ as $(N, T) \rightarrow \infty$. Hsiao and Zhou (2018) show that using the Chamberlain's approach to condition the effects on observed explanatory variables can reduce the order of asymptotic bias to $\sqrt{N / T^{3}}$. On the other hand, they show that the QMLE with a properly modeled initial value distribution combined with Chamberlain's approach is consistent and asymptotically unbiased whether $T$ is fixed or goes to infinity as long as $N \rightarrow \infty$. For our specification $y_{i t}=\rho y_{i, t-1}+z_{i t}^{\prime} \theta+\varpi_{i}+u_{i t}$, the used QMLE estimator with the xtdpdqml Stata command iterates the initial observations continuously backward in time as: $y_{i 0}=\rho^{m} y_{i,-m}+\sum_{s=0}^{m-1} \rho^{s} z_{i,-s}^{\prime} \theta+$ $\frac{1-\rho^{m}}{1-\rho} \varpi_{i}++\sum_{s=0}^{m-1} \rho^{s} u_{i,-s}$ with $m \rightarrow \infty$. The last right three terms of the previous equation imply a restriction on the covariance between the initial observations and the unit-specific effects: $\phi \sigma_{0}^{2}=\sigma_{\varpi}^{2} /(1-\rho)$ with $\sigma_{0}^{2}=$ $\left(\sigma_{\varpi}^{2}+\sigma_{u}^{2}\right) /(1-\rho)^{2}$. Feasible starting values for the variance parameters $\left(\sigma_{\varpi}^{2}, \sigma_{u}^{2}, \sigma_{0}^{2}, \phi\right)$ need to satisfy the restriction $\left(\sigma_{\varpi}^{2}-\phi^{2} \sigma_{0}^{2}\right) T>-\sigma_{u}^{2}$ (see Kripfganz (2016)). We use the following starting values $\left(\sigma_{\varpi}^{2}, \sigma_{u}^{2}, \sigma_{0}^{2}, \phi\right)=(0.1,0.2,0.2,0.2)$ which allow to get unbiased QMLE.
    ${ }^{21}$ Again, the mixture approach for calculating the standard errors considerably reduces the computation time. For $N=200$ and $T=30$, it decreases from 2708 seconds to 254 seconds - a reduction by a factor of 10.7 - and the differences with the bootstrap approach are marginal (see Table C. 4 in the supplementary material).

[^9]:    ${ }^{22}$ For the following specification: $y_{i t}=\rho y_{i, t-1}+x_{i t}^{\prime} \beta+V_{i}^{\prime} \eta+\mu_{i}+u_{i t}$, the first stage model is $y_{i t}=\rho y_{i, t-1}+$ $x_{i t}^{\prime} \beta+\bar{\kappa}+e_{i t}$, where $e_{i t}=\kappa_{i}-\bar{\kappa}+u_{i t}, \kappa_{i}=V_{i}^{\prime} \eta+\mu_{i}, \bar{\kappa}=E\left[\kappa_{i}\right]$ and is estimated in first differences. In the second stage, Kripfganz and Schwarz (2019) estimate the coefficients $\eta$ based on the level relationship: $y_{i t}-\widehat{\rho} y_{i, t-1}-x_{i t}^{\prime} \widehat{\beta}=$ $V_{i}^{\prime} \eta+\vartheta_{i t}$ where $\vartheta_{i t}=\mu_{i}+u_{i t}+(\widehat{\rho}-\rho) y_{i, t-1}-x_{i t}^{\prime}(\widehat{\beta}-\beta)$ and compute proper standard errors with an analytical correction term.
    ${ }^{23}$ Following Kripfganz and Schwarz (2019), we use successively these two Stata commands (xtdpdqml and xtseqreg). Unfortunately, these Stata commands do not give the residual variance of specific effects $\sigma_{\mu}^{2}$ but only $\sigma_{u}^{2}$.
    ${ }^{24}$ As with previous estimators, the mixture approach for calculating the standard errors considerably reduces the computation time. For $N=200$ and $T=10$, it shrinks from 1183 seconds to as litle as 106 seconds - a reduction by a factor of 11 - although the standard errors differ marginally from those of the bootstrap approach (see Table C. 5 in the supplementary material).

[^10]:    ${ }^{25}$ We use our own R codes for our Bayesian estimator and the xtdcce2 Stata package for the CCEP estimator. We use the same DGP set under R and Stata environments to compare the two methods.
    ${ }^{26}$ Once again, the use of the mixture approach for the calculation of the standard errors considerably reduces the computation time. For $N=100, T=30$ (resp. $N=50, T=50$ ), it goes from 1775 to 106 seconds (resp. from 1901 seconds to 113 seconds) - a sizable factor (16.6 and 16.8, respectively) - and differences with the bootstrap approach are minimal (see Table C. 6 in the supplementary material).

[^11]:    ${ }^{27}$ i.e., the demeaned time means.
    ${ }^{28}$ The dynamic CCEP estimator is defined as: $y_{i t}=\rho y_{i, t-1}+x_{i t} \beta_{1}+x_{i, t-1} \beta_{2}+\sum_{j=0}^{p_{T}^{T}} f_{t-j}^{*} \gamma_{i, j}+u_{i t}$ where $p_{T}=T^{1 / 3}$ (see Chudik and Pesaran (2015b) pp. 26). Then, $p_{T} \approx 3$ when $T=30$ or $T=50$. In the simulations, we use $p_{T}=0$.
    ${ }^{29}$ See Table B. 6 in the supplementary material for $N=50, T=50$.
    ${ }^{30}$ The mixture approach for the calculation of the standard errors once again reduces considerably the computation time. For $N=100, T=30$ (resp. $N=50, T=50$ ), it goes from 1996 seconds to 344 seconds (resp. from 1820 seconds to 177 seconds) - a reduction factor of between 5.8 and 10.3 - and differences with the bootstrap approach are minimal (see Table C. 7 in the supplementary material).
    ${ }^{31}$ We use our own $R$ codes for our Bayesian estimator and the xtdcce2 Stata package for the CCEMG estimator. We use the same DGP set under R and Stata environments to compare the two methods.

[^12]:    ${ }^{32}$ See Table B. 6 in the supplementary material for $N=50, T=50$.
    ${ }^{33}$ The mixture approach once again is highly efficient. For $N=100, T=30$ (resp. $N=50, T=50$ ), computation time decreases from 3059 to 159 seconds (resp. from 1566 seconds to 177 seconds) - a reduction factor of between 8.8 and 19.2 - although small differences between the estimated standard errors remain (see Tables C. 8 and C. 9 in the supplementary material).
    ${ }^{34}$ See the supplementary material.
    ${ }^{35}$ See the supplementary material.

[^14]:    ${ }^{1}$ The Euler integral formula is given by:

    $$
    \int_{0}^{1}(t)^{a_{2}-1}(1-t)^{a_{3}-a_{2}-1}(1-z t)^{-a_{1}} d t=\frac{\Gamma\left(a_{2}\right) \Gamma\left(a_{3}-a_{2}\right)}{\Gamma\left(a_{3}\right)} \times{ }_{2} F_{1}\left(a_{1} ; a_{2} ; a_{3} ; z\right)
    $$

[^15]:    ${ }^{2}$ A random variable $X \in \mathbb{R}^{p}$ has a multivariate Student distribution with location parameters $\mu$, shape matrix $\Sigma$ and $\nu$ degrees of freedom, $X \sim t_{\nu}(\mu, \Sigma)$ if its pdf is given by

    $$
    \frac{\Gamma\left(\frac{\nu+p}{2}\right)}{\Gamma\left(\frac{\nu}{2}\right)(\nu \pi)^{\frac{p}{2}}|\Sigma|^{\frac{1}{2}}}\left[1+\frac{1}{\nu}(x-\mu)^{\prime} \Sigma^{-1}(x-\mu)\right]^{-\frac{\nu+p}{2}}
    $$

[^16]:    4 "If $X$ has the p-variate $t$ distribution with degrees of freedom $\nu$, mean vector $\mu$, and correlation matrix $R$, then, for any nonsingular scalar matrix $C$ and for any $a, C X+a$ has the p-variate $t$ distribution with degrees of freedom $\nu$, mean vector $C \mu+a$, and correlation matrix $C R C^{\prime}$." (Kotz and Nadarajah (2004), p.15).
    ${ }^{5} \mathrm{OLS}: y=Z \theta+\nu$ with $Z=\left[y_{-1}, X\right], \theta=\left(\rho, \beta^{\prime}\right)^{\prime}, \nu=Z_{\mu} \mu+u$ and LSDV: $y=Z \theta+u$ with $Z=\left[y_{-1}, X, Z_{\mu}\right]$, $\theta=\left(\rho, \beta^{\prime}, \mu^{\prime}\right)^{\prime}$.

[^17]:    2 S boot: two-stage with individual block resampling bootstrap.

[^18]:    ${ }^{6}$ The $R$ function chol2inv (chol(X)) instead of the standard function solve(X) for a symmetric definite positive $X$ matrix.
    ${ }^{7}$ Using the rmvn. sparse command in the sparseMVN R package.

[^19]:    ${ }^{8}$ In other words, $k_{2}=1$ for the RE, Chamberlain and Hausman-Taylor worlds. $k_{2}=m$ for the common trends world and the common correlated effects world.
    ${ }^{9} \Gamma$ is given in sections 3.1.4 and 3.1.6 in the main text.
    ${ }^{10}$ Table C. 1 reports the results of fitting the Bayesian two-stage (B2S) model with block resampling bootstrap (se_boot) and mixture of $t$-distributions (se_mixt) for estimating the standard errors along with those from the GMM and QMLE, each in a separate panel respectively for $(N=100, T=10)$ and $(N=200, T=30)$. The true parameter values appear on the first line of the Table. The last column reports the computation time in seconds.

[^20]:    ${ }^{11} \gamma_{i}$ is given in sections 3.1.4 and 3.1.6 in the main text.
    ${ }^{12}$ In their simulation study, Chudik and Pesaran (2015) use $0.2 \leq N / T \leq 5$. They also use a jackknife bias correction and a recursive mean adjustment correction of the CCEMG estimator.
    ${ }^{13}$ We do not report the GMM estimation since it takes more than 50,000 seconds!

[^21]:    ${ }^{14}$ This exercise could be conducted for the other worlds such as the Chamberlain-type fixed effects or HausmanTaylor world but we report the results for only two worlds for the sake of brevity.
    ${ }^{15}$ From a theoretical point of view, and under the null, $H_{0}: \varepsilon=0$, it follows that the weights $\widehat{\lambda}_{\theta, g_{0}}=1$ and $\widehat{\lambda}_{b, h_{0}}=1$ so that the restricted ML-II estimator of $\theta$ is given by $\widehat{\theta}_{\text {restrict }}=\theta_{*}\left(b \mid g_{0}\right)$. Under $H_{1}: \varepsilon \neq 0$ the unrestricted estimator is $\widehat{\theta}_{\text {unrestrict }}\left(\equiv \widehat{\theta}_{M L-I I}\right)=\widehat{\lambda}_{\theta, g_{0}} \theta_{*}\left(b \mid g_{0}\right)+\left(1-\widehat{\lambda}_{\theta, g_{0}}\right) \theta_{E B}\left(b \mid g_{0}\right)$. The restricted ML-II estimator $\theta_{*}\left(b \mid g_{0}\right)$ is the Bayes estimator under the base prior $g_{0}$.

[^22]:    ${ }^{16}$ The Skewed $t$ distribution with $\nu$ degrees of freedom and skewing parameter $\gamma$ has the following density:

    $$
    p d f(x)=\frac{2}{\gamma+\frac{1}{\gamma}} f(z) \text { where } z=\gamma x \text { if } x<0 \text { or } z=x / \gamma \text { if } x \geq 0
    $$
